United States Environmental Protection Agency

November 2012
EPA/600/R-10/075C

Integrated Science Assessment for Lead

(Third External Review Draft)

National Center for Environmental Assessment-RTP Division
Office of Research and Development
U.S. Environmental Protection Agency
Research Triangle Park, NC

DISCLAIMER

This document is the third external review draft for review purposes only and does not constitute U.S. Environmental Protection Agency policy. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

CONTENTS

Lead Project Team

Executive Direction

Dr. John Vandenberg (Director)—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Debra Walsh (Deputy Director)—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Mary Ross (Branch Chief)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Reeder Sams (Acting Deputy Director)—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Doug Johns (Acting Branch Chief)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Scientific Staff

Dr. Ellen Kirrane (Team Leader, ISA for Lead)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. James Brown—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Allen Davis—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jean-Jacques Dubois—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Tara Greaver—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Erin Hines—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Dennis Kotchmar—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Meredith Lassiter—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen McDow—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Qingyu Meng—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Elizabeth Oesterling Owens—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Molini Patel—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr Joseph P. Pinto—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lindsay Stanek—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Svendsgaard—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lisa Vinikoor-Imler—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Technical Support Staff

Ms. Marieka Boyd—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Kenneth J. Breito–Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ellen Lorang—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. J. Sawyer Lucy–Student Services Authority, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Deborah Wales—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Richard N. Wilson–National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Barbara Wright—Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Authors, Contributors, and Reviewers

Authors

Dr. Ellen Kirrane (Team Leader, ISA for Lead)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Robyn Blain— Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Lexington, MA

Dr. James Brown—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Philip Bushnell, National Health and Environmental Effects Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Allen Davis—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Gary Diamond—Syracuse Research Corporation, Akron, NY

Dr. Rodney Dietert—Cornell University College of Veterinary Medicine, Veterinary Medical Center, Ithaca, NY

Dr. Jean-Jacques Dubois—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Anne Fairbrother—Exponent, Inc., Bellevue, WA

Dr. Jay Gandy—Department of Environmental and Occupational Health, University of Arkansas for Medical Sciences, Little Rock, AR

Dr. Harvey Gonick—David Geffen School of Medicine, University of California-Los Angeles, Los Angeles, CA

Dr. Margaret Graham—School of Geosciences, University of Edinburgh, Edinburgh, Scotland

Dr. Tara Greaver—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Erin Hines—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Dennis Kotchmar—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Meredith Lassiter—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen McDow—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Qingyu Meng—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Bill Mendez—Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Fairfax, VA

Dr. Howard Mielke—Center for Bioenvironmental Research, Tulane/Xavier Universities, New Orleans, LA

Ms. Chandrika Moudgal— Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Dublin, CA

Dr. Elizabeth Oesterling Owens—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Katherine Palmquist—Exponent, Inc., Bellevue, WA

Dr. Molini Patel—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr Joseph P. Pinto—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen Rothenberg—National Institute of Public Health, Cuernavaca, Morelos, Mexico

Dr. MaryJane Selgrade—Energy, Environment and Transportation, Environmental Science & Policy, ICF International, RTP, NC

Dr. Lindsay Stanek—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Svendsgaard—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lisa Vinikoor-Imler—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Virginia Weaver—Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Dr. Marc Weisskopf—Department of Environmental Health and Department of Epidemiology, Harvard School of Public Health, Harvard University, Boston, Massachusetts

Dr. John Pierce Wise, Sr.—Maine Center for Toxicology and Environmental Health, Department of Applied Medical Sciences, Portland, ME

Dr. Rosalind Wright—Harvard Medical School and School of Public Health, Harvard University, Boston, MA

Dr. Robert Wright—Harvard Medical School and School of Public Health, Harvard University, Boston, MA

Contributors

Mr. Brian Adams—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Halil Cakir— Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ye Cao—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Laura Datko—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Josh Drukenbrod—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, RTP, NC

Ms. Meagan Madden—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Mark Schmidt—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Katie Shumake—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Kaylyn Siporin—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Lauren Tuttle—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Adrien Wilkie—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Brianna Young—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Reviewers

Dr. David Bellinger – Harvard Medical School and Department of Environmental Health, Harvard School of Public Health, Boston, MA

Dr. Christal Bowman—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Buchwalter—Department of Toxicology, North Carolina State University, Raleigh, NC

Dr. Barbara Buckley—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Kevin Cavender—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Rebecca C. Dzubow—Office of Children's Health Protection, U.S. Environmental Protection Agency, Washington, DC

Dr. David DeMarini—National Health and Environmental Effects Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Pam Factor-Litvak—Department of Epidemiology, Mailman School of Public Health, New York, NY

Dr. Gabriel Filippelli—Department of Earth Sciences, Indiana University-Purdue University, Indianapolis, IN

Dr. Andrew Friedland—Environmental Studies Program, Dartmouth College, Hanover, NH

Dr. Barbara Glenn—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Washington, DC

Dr. Jeff Herrick—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Marion Hoyer—Office of Transportation and Air Quality, Office of Air and Radiation, U.S. Environmental Protection Agency, Ann Arbor, MI

Dr. Joseph Jacobson – Department of Psychiatry and Behavioral Neurosciences, Wayne State University, Detroit, MI

Dr. Douglas Johns—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jay S. Kaufman – Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Canada

Dr. Thomas Luben—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Karen Martin—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Connie Meacham—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Marie Lynn Miranda—Environmental Sciences and Policy, Nicholas School of the Environment, Duke University, Durham, NC

Dr. Deirdre Murphy—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Paul Mushak—PB Associates, Durham NC

Dr. Kris Novak—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. David Orlin—Air and Radiation Law Office, Office of General Counsel, U.S. Environmental Protection Agency, Washington, DC

Dr. Meredith Pedde—Office of Transportation and Air Quality, Office of Air and Radiation, U.S. Environmental Protection Agency, Ann Arbor, MI

Dr. Pradeep Rajan—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Joanne Rice—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Mary Ross—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Joel Schwartz—Department of Environmental Health, Harvard School of Public Health, Boston, MA

Mr. Jason Sacks—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ginger Tennant—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jay Turner—Environmental and Chemical Engineering Department, Washington University, St. Louis, MO

Dr. John Vandenberg—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Robert W. Vanderpool—National Exposure Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Nosratola Vaziri—Division of Nephrology and Hypertension, School of Medicine, University of California, Irvine, Irvine, CA

Ms. Debra Walsh—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Nasser Zawia—Department of Biomedical and Pharmaceutical Sciences, University of Rhode Island, Kingston, RI

Clean Air Scientific Advisory Committee Lead NAAQS Review Panel

Chair of the Lead Review Panel

Dr. Christopher H. Frey*, North Carolina State University, Raleigh, NC

Lead Review Panel Members

Mr. George A. Allen*, Northeast States for Coordinated Air Use Management (NESCAUM), Boston, MA

Dr. Herbert Allen, University of Delaware, Newark, DE

Dr. Richard Canfield, Cornell University, Ithaca, NY

Dr. Deborah Cory-Slechta, University of Rochester, Rochester, NY

Dr. Cliff Davidson, Syracuse University, Syracuse, NY

Dr. Philip E. Goodrum, Cardno ENTRIX, Syracuse, NY

Dr. Sean Hays, Summit Toxicology, Allenspark, CO

Dr. Philip Hopke, Clarkson University, Potsdam, NY

Dr. Chris Johnson, Syracuse University, Syracuse, NY

Dr. Susan Korrick, Harvard Medical School, Boston, MA

Dr. Michael Kosnett, University of Colorado School of Medicine, Denver, CO

Dr. Roman Lanno, Ohio State University, Columbus, OH

Mr. Richard L. Poirot, Vermont Agency of Natural Resources, Waterbury, VT

Dr. Joel Pounds, Pacific Northwest National Laboratory, Richland, WA

Dr. Michael Rabinowitz, Marine Biological Laboratory, Newport, RI

Dr. William Stubblefield, Oregon State University, Corvallis, OR

Dr. Ian von Lindern, TerraGraphics Environmental Engineering, Inc., Moscow, ID

Dr. Gail Wasserman, Columbia University, New York, NY

Dr. Michael Weitzman, New York University School of Medicine, New York, NY

* Members of the statutory Clean Air Scientific Advisory Committee (CASAC) appointed by the EPA Administrator

Science Advisory Board Staff

Mr. Aaron Yeow, Designated Federal Officer, U.S. Environmental Protection Agency, Science Advisory Board (1400R), 1200 Pennsylvania Avenue, NW, Washington, D.C. 20460-0001, Phone: 202-564-2050, Fax: 202-565-2098, (yeow.aaron@epa.gov)

Acronyms and Abbreviations

α	alpha
αT	the extent of DNA denaturation per cell
Å	Ångström (10^{-10} meter)
AA	African American; arachidonic acid, atomic absorption
AALM	All Ages Lead Model
AAS	atomic absorption (spectrophotometry, spectrometry, spectroscopy)
Ab	amyloid-beta peptide
ABL	atmospheric boundary layer
ACE	angiotensin converting enzyme
ACF	Apalachicola, Chattahoochee, and Flint River Basin
ACh	acetylcholine
ACP	acid phosphatase
ACR	acute to chronic ratio
Acyl-CoA	acyl-coenzyme A
AD	axial diffusivity
ADHD	attention deficit hyperactivity disorder
ADP	adenosine diphosphate
AE	anion exchanger
AEC	adenylate energy charge
AERMOD	atmospheric dispersion model
AF	absorbed fraction; absorption fraction
aff'd	affirmed
A/G	albumin/globulin
Ag	silver
AGL	above-ground level
A-horizon:	Topsoil horizon (surface soil)
AKI	acute kidney injury
Al	aluminum
ALA	aminolevulinic acid
ALAD	aminolevulinic acid dehydratase;
ALAD 1-1:	aminolevulinate delta-dehydratase 1-1
ALAD-2	aminolevulinate delta-dehydratase-2
ALD	aldehyde dehydrogenase
ALM	Adult Lead Methodology
ALP	alkaline phosphatase
ALS	Amyotrophic Lateral Sclerosis (Lou Gehrig's disease)
ALT	alanine aminotransferase
AM	Alveolar macrophages
AMF	arbuscular mycorrhizal fungi
AMP	adenosine monophosphate
ANC	acid neutralizing capacity; absolute neutrophil counts
ANF	atrial natriuretic factor
AngII	renal angiotensin II
ANOVA	analysis of variance
ANPR	advance notice of proposed rulemaking
AOP	adverse outcome pathway
AP-1	activator protein-1
ApaI	polymorphism of the VDR in humans
APC	antigen-presenting cell
APOE	Apolipoprotein E
APRT	adenine phosphoribosyltransferase
AQCD	Air Quality Criteria Document
AQS	(U.S. EPA) Air Quality System (database)
Ar	argon
As	arsenic
AST	aspartate aminotransferase
ASV	anode stripping voltammetry
ATLD	ataxia-telangiectasia-like disorder
ATOFMS:	aerosol time-of-flight mass spectrometry
ATP	adenosine-triphosphate
ATPase	adenosine triphosphatase; adenosine triphosphate synthase
ATS	American Thoracic Society
ATSDR	Agency for Toxic Substances and Disease Research

Au gold

avg average

AVS acid-volatile sulfides

a-wave initial negative deflection in the electroretinogram

AWQC Ambient Water Quality Criteria

β Beta; Beta coefficient; regression coefficient; standardized coefficient

3β-HSD 3-beta-hydroxysteroid dehydrogenase

17β-HSD: 17-beta-hydroxysteroid dehydrogenase

Ba barium

BAF bioaccumulation factors

BAL 2,3-dimercaptopropanol

BASC Behavior Assessment System for Children

BASC-PRS: Behavior Assessment System for Children-Parent Ratings Scale

BASC-TRS: Behavior Assessment System for Children-Teacher Rating Scale

BC black carbon, soot

BCB blood cerebrospinal fluid barrier

B-cell Bone marrow-derived lymphocytes, B lymphocyte

BCF bioconcentration factors

Bcl-x member of the B-cell lymphoma-2 protein family

Bcl-xl B-cell lymphoma-extra large

B-horizon: subsoil horizon

bio biological

Bi_2S_3 bismuth (III) sulfide

BK biokinetics

BLM biotic ligand model

BMD benchmark dose; bone mineral density

BMDL benchmark dose limit

BMI body mass index

BMP bone morphogenetic protein

BMS Baltimore Memory Study

BMW battery manufacturing workers

BP blood pressure

Br bromine

BR bronchial responsiveness

BrdU bromo-2'-deoxyuridine

8-Br-GMPc: 8-bromo-cyclic guanosine monophosphate

Bs-horizon; subsoil horizon with accumulation of sesquioxides

BSI Brief Symptom Inventory

BSID-II Bayley Scale for Infant Development-II

BsmI polymorphism of the VDR in humans

Bt20 Birth-to-age Twenty (cohort)

BUN blood urea nitrogen

bw body weight

b-wave initial positive deflection in the electroretinogram

C carbon; Celsius; soil or dry sediment Pb concentration; Caucasian; Cysteine

Ca calcium

Ca^{2+} calcium ion

CAA Clean Air Act

CaBP calcium binding protein

$CaCl_2$ calcium chloride

$CaCO_3$ calcium carbonate; calcite

CaEDTA calcium ethylenediaminetetraacetic acid

CaMKII calmodulin-dependent protein kinase II

cAMP cyclic adenosine monophosphate

CASAC Clean Air Scientific Advisory Committee

CASM Comprehensive Aquatic Systems Model

$CaSO_4$ calcium sulfate

$CaSO_4 \cdot 2H_2O$: gypsum

CAT catalase

CBLI cumulative blood Pb index

CBSA core based statistical area

CCSEM computer-controlled scanning electron microscopy

CD cluster of differentiation

Cd cadmium

Cd(II) cadmium (II)

Cd^{2+} cadmium ion

CD3+ T lymphocyte

CD4+ T helper cell

CDC Centers for Disease Control

CEA carcinoembryonic antigen

CEC cation exchange capacity

cent central

cert. certiorari

cf correction factor; latin abbreviation for conferre (used as "compared with)

CFL constant flux layer

CFR Code of Federal Regulations

cGMP cyclic guanosine monophosphate

C-H carbon-hydrogen (bond)

CHAD Consolidated Human Activity Database

ChAT chlorine acetyltransferase

CHD coronary heart disease

CHL Chinese hamster lung

CHO Chinese hamster ovary cell line

C-horizon:
Soil horizon underneath A- and B-horizons, may contain lumps or shelves of rock and parent material

CHV79 Chinese hamster lung cell line

CI confidence interval

Cir. circuit

CKD chronic kidney disease

CKD-EPI:
Chronic Kidney Disease Epidemiology Collaboration

CL confidence limit

Cl chlorine

Cl^- chlorine ion

Cl_2 molecular chlorine

CLACE 5:
Fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere campaign

CLS Cincinnati Lead Study

CO carbon monoxide

CO_2 carbon dioxide

CO_3^{2-} carbonate ion

Co cobalt

CoA coenzyme A

COD coefficient of difference

Coeff coefficient

COMP aT:
The percentage of sperm with increased sensitivity to DNA denaturation

Con control

Conc. concentration

Cong. congress

Corr correlation

COX cyclooxygenase; cytochrome oxidase subunits

COX-2 cyclooxygenase-2

$cPLA_2$ cytosolic phospholipidase A_2

CPRI coarse particle rotary impactor

CPRS-R
Conners' Parent Rating Scale-Revised

Cr chromium; creatine

C-R concentration-response (relaltionship)

Cr III chromium III

CRAC Ca^{2+} release activated calcium

CRACI calcium release activated calcium influx

CREB cyclic adenosinemonophosphate (cAMP) response element-binding

CRP C-reactive protein

CSF colony-stimulating factor

CSN Chemical Speciation Network

CT zinc-adequate control

Cu copper

Cu(II) copper (II)

CV coefficient of variation

CVD cardiovascular disease

CYP cytochrome

CYP 1A1, Cyp1A1:
cytochrome P450 family 1 member A1

CYP 1A2, Cyp1A2:
cytochrome P450 family 1 member A2

CYP P450:
cytochrome P450

Δ delta, difference, change

Δ5-3β-HSD :
delta-5-3-beta-hydroxysteroid dehydrogenase

δ-ALA
5-aminolevulinic acid; delta-aminolevulinic acid

δ-ALAD : delta-aminolevulinic acid dehydratase

D_2, D_3 dopamine receptors

D50 size at 50% efficiency

d day(s); depth

db, dB decibel

DbH dopamine beta-hydroxylase

DBP diastolic blood pressure

DENA Denali National Park and Preserve, Alaska

dep dependent

dev. deviation

DEX exogenous dexamethasone

DG degenerate gyrus

2-dG 2-deoxyguanosine

DHAA dehydroascorbate

diff differentiation

DIT developmental immunotoxicity

DMPS 2,3-dimercaptopropane-l-sulfonic acid

DMSA dimercaptosuccinic acid

DMSO dimethyl sulfoxide

DNA deoxyribonucleic acid

DoAD developmental origins of adult disease

DOC dissolved organic carbon

DOM dissolved organic matter

DP-109 metal chelator

DP-460 metal chelator

DR diet-restricted

DRD4 dopamine 4 receptor

DRD4.7 dopamine 4 receptor repeat alleles

DRUM Davis Rotating Unit for Monitoring

D-serine neuronal signal

DSM-IV Diagnostic Statistical Manual-IV

DTH delayed-type hypersensitivity

DTPA diethylene triamine pentaacetic acid; technetium-diethylenetriamine-pentaacetic acid

E east; expression for exposure

E2 estradiol

e exponential function

EC elemental carbon, endothelial cell

EC_{10} effect concentration for 10% of test population

EC_{20} effect concentration for 20% of test population

EC_{50} effect concentration for 50% of test population

ECG electrocardiography; electrocardiogram

ECOD 7-ethoxycoumarin-o-deethylase

Eco-SSLs: ecological soil screening levels

ED_{10} effect dose for 10% of population

EDTA ethylenediaminetetraacetic acid

EFS electrical field stimulus

EGF epidermal growth factor

EGFR epidermal growth factor receptor

eGFR estimated glomerular filtration rate

Eh electrochemical potential

E-horizon: Eluviated horizon; soil horizon which is eluviated or leached of mineral and/or organic content

EI-MS electron impact ionization mass spectrometry

ELPI electrical low-pressure impactor

eNOS endothelial nitric oxide synthase

EOG end-of-grade

EPA U.S. Environmental Protection Agency

EPT ephemeroptera, plecoptera, trichoptera

ER endoplasmic reticulum

Erg-1 ether-a-go-go related gene

ERG electroretinogram

ERK extracellular signal regulated kinase

ERK1/2 extracellular signal-regulated kinases 1 and 2

EROD 7-ethoxyresorufin-o-deethylase

ESCA electron spectroscopy for chemical analysis

ESI-MS electrospray ionization mass spectrometry

ESRD end stage renal disease

ET endothelin

ET-1 vasoconstrictor endothelin-1

ET_A-type receptors: endothelin type A receptors

ETS environmental tobacco smoke

EU European Union

EURO	European emission standard
eV	electronvolts
EXAFS	X-ray absorption fine structure spectroscopy
F_0	filial "zero" generation (parental stock)
F_1	first filial generation (offspring of F_0)
F_2	second filial generation (offspring of F_1)
FAA	Federal Aviation Agency
FAI	free androgen index
FAS	apoptosis stimulating fragment
Fas-L	apoptosis stimulating fragment ligand
Fe	iron
Fe(III)	iron III
FEM	Federal equivalence method
FEV1	forced expiratory volume in 1 second
FI	fixed interval
FI-Ext	fixed interval with extinction
Fl	fluoride
FokI	polymorphism of the VDR in humans
FR	Federal Register (Notice)
FrA	fractional anisotropy
FR-FI	fixed ratio-fixed interval
FRM	Federal reference method
FSH	follicle-stimulating hormone
FSIQ	full scale intelligence quotient (IQ)
FT3	free triiodothyronine
FT4	free thyroxine
G	pregnancy; guanine
G2	gap 2 Phase
g, kg, mg, μg, ng, pg:	gram(s), kilogram(s), milligram(s), microgram(s), , nanogram(s), picogram(s)
G93A	mouse model
GAAR	Gates of the Arctic National Park and Preserve, Alaska
GABA	γ-aminobutyric acid; gamma aminobutyric acid
GABAergic:	inhibitory neurons that relase the neurotransmitter GABA
GAD	generalized anxiety disorder
GC	gas chromatography
G-CSF	granulocyte colony-stimulating factor
GD	gestational day
GEE	generalized estimating equations
GFAAS	graphite furnace atomic absorption spectrometry
GFAP	glial fibrillary acidic protein
GFR	glomerular filtration rate
GGT	gamma-glutamyl transpeptidase
GH	growth hormone
GHRH	growth-hormone releasing hormone
GI	gastrointestinal
GIS	Geographic Information System
G+L	pregnancy plus lactation
GLAC	Glacier National Park, Montana
GLE	gestationally-lead exposed
GM	geometric mean
GMR	geometric mean blood Pb ratio
GnRH	gonadotropin-releasing hormone
G6PD	glucose-6-phosphate dehydrogenase
GPEI	glutathione transferase P (GST-P) enhancer I
GPT	glutamate pyruvate transaminase
GPx	glutathione peroxidase
GPX1	gene encoding for glutathione peroxidase 1
GR	glutathione reductase
GRP78	glucose-regulated protein 78
GRP94	glucose-regulated protein 94
Grp	glucose-regulated protein
GSD	geometric standard deviation
GSH	glutathione
GSSG	glutathione disulfide
GST	glutathione S-transferase
GSTM1	glutathione S-transferase Mu 1
GST-P	glutathione transferase P
GTP	guanosine-5'-triphosphate; guanine triphosphate
H	hydrogen
H^+	hydrogen ion
h	hour(s)
ha	hectare
HAD	hydroxy-alkenals
HAP	hazardous air pollutant

Hb hemoglobin

HC_5 acute toxicity hazardous concentration for 5% of species

HC_{10} acute toxicity hazardous concentration for 10% of species

HCl hydrochloric acid

HCO_3^- bicarbonate; hydrogen carbonate

Hct hematocrit

HDL high-density lipoprotein

HERO Heatlh and Environmental Research online (database)

HEW U.S. Department of Health, Education, and Welfare

HF hydrogen fluoride

HFE hemochromatosis gene

HFE C282Y: hemochromatosis gene with C282Y mutation

HFE H63D : hemochromatosis gene with H63D mutation

Hg mercury

$HgCl_2$ mercury(II) chloride

5-HIAA 5-hydroxyindoleacetic acid

HIV human immunodeficiency virus

HLA-DRB: human leukocyte antigen genes

HMEC human dermal microvascular endothelial cells

HMGR 3-hydroxy-3-methylglutaryl-CoA reductase

HMOX-1: heme oxygenase-1

HNO_3 nitric acid

HO-1 heme oxygenase; heme oxidase-1

H_2O water

H_2O_2 hydrogen peroxide

HOME Home Observation for Measurement of the Environment

HPA hypothalamic-pituitary-adrenal

HPb, h-Pb: high Pb

HPG hypothalamic-pituitary-gonadal

HPLC high-performance liquid chromatography

HPRT hypoxanthine-guanine phosphoribosyltransferase

HPT hyperparathyroidism; hypothalamic-pituitary-thyroid

HR heart rate; hazard ratio

HRV heart rate variability

hsp heat shock proteins

5HT serotonin

5-HT 5-hydroxytryptamine

5-HT2B 5-hydroxytryptamine receptor 2B

hTERT telomerase reverse transcriptase

HVA homovanillic acid

I interstate

IARC International Agency for Research on Cancer

IC_{50} half maximal inhibitory concentration

ICAP inductively coupled argon plasma

ICP-AES Inductively coupled plasma atomic emission spectroscopy

ICPMS, ICP-MS: Inductively coupled plasma mass spectrometry

PM particulate matter

PM_X Particulate matter of a specific size range not defined for regulatory use. Usually X refers to the 50% cut point, the aerodynamic diameter at which the sampler collects 50% of the particles and rejects 50% of the particles. The collection efficiency, given by a penetration curve, increases for particles with smaller diameters and decreases for particles with larger diameters. The definition of PM_X is sometimes abbreviated as "particles with a nominal aerodynamic diameter less than or equal to X μm" although X is usually a 50% cut point.

PM_{10} In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm; a measurement of thoracic particles (i.e., that subset of inhalable particles thought small enough to penetrate beyond the larynx into the thoracic region of the respiratory tract) in regulatory terms, particles with an upper 50% cut-point of 10± 0.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix J of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53 or by an equivalent method designated in accordance with 40 CFR Part 53.

$PM_{2.5}$ In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; a measurement of fine particles in regulatory terms, particles with an upper 50% cut-point of 2.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix L of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53, by an equivalent method designated in accordance with 40 CFR Part 53, or by an approved regional method designated in accordance with Appendix C of 40 CFR Part 58.

$PM_{10\text{-}2.5}$ In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal 2.5 μm; a measurement of thoracic coarse particulate matter or the coarse fraction of PM_{10} in regulatory terms, particles with an upper 50% cut-point of 10 μm aerodynamic diameter and a lower 50% cut-point of 2.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) as measured by a reference method based on Appendix O of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53 or by an equivalent method designated in accordance with 40 CFR Part 53.

PM_{10C} The $PM_{10\text{-}2.5}$ concentration of $PM_{10\text{-}2.5}$ measured by the 40 CFR Part 50 Appendix O reference method which consists of currently operated, co-located low-volume (16.7 Lpm) PM_{10} and $PM_{2.5}$ reference method samplers.

Preamble

Process of ISA Development

This preamble outlines the general process for developing an Integrated Science Assessment (ISA) including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments. The ISA provides a concise review, synthesis, and evaluation of the most policy-relevant science to serve as a scientific foundation for the review of the National Ambient Air Quality Standards (NAAQS). The general process for NAAQS reviews is described at http://www.epa.gov/ttn/naaqs/review.html. Figure I depicts the general NAAQS review process and information for individual NAAQS reviews is available at www.epa.gov/ttn/naaqs. This preamble is a general discussion of the basic steps and criteria used in developing an ISA; for each ISA, specific details and considerations are included in the introductory section for that assessment.

The fundamental process for developing an ISA includes:

- literature searches;
- study selection;
- evaluation and integration of the evidence; and
- development of scientific conclusions and causal judgments.

An initial step in this process is publication of a call for information in the Federal Register that invites the public to provide information relevant to the assessment, such as new or recent publications on health or welfare[1] effects of the pollutant, or from atmospheric and exposure sciences fields. The U.S. Environmental Protection Agency (EPA) maintains an ongoing literature search process for identification of relevant scientific studies published since the last review of the NAAQS. Search strategies are designed for pollutants and scientific disciplines and iteratively modified to optimize identification of pertinent publications. Papers are identified for inclusion in several additional ways: specialized searches on specific topics; independent review of tables of contents for journals in which relevant papers may be published; independent identification of relevant literature by expert scientists; review of citations in previous assessments and identification by the public and the Clean Air Scientific Advisory Committee (CASAC) during the external review process. This literature search and study selection process is depicted in Figure II. Publications considered for inclusion in the ISA

[1] Welfare effects as defined in Clean Air Act (CAA) Section 302(h) [42 U.S.C. 7602(h)] include, but are not limited to, "effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being."

are added to the Health and Environmental Research Online (HERO) database developed by EPA (http://hero.epa.gov/); the references in the ISA include a hyperlink to the database.

Studies that have undergone scientific peer review and have been published or accepted for publication and reports that have undergone review are considered for inclusion in the ISA. Analyses conducted by EPA using publicly available data are also considered for inclusion in the ISA. All relevant epidemiologic, controlled human exposure, toxicological, and ecological and welfare effects studies published since the last review are considered, including those related to exposure-response relationships, mode(s) of action (MOA), and potentially at-risk populations and lifestages. Studies on atmospheric chemistry, environmental fate and transport, dosimetry, toxicokinetics and exposure are also considered for inclusion in the document, as well as analyses of air quality and emissions data. References that were considered for inclusion in a specific ISA can be found using the HERO website (http://hero.epa.gov).

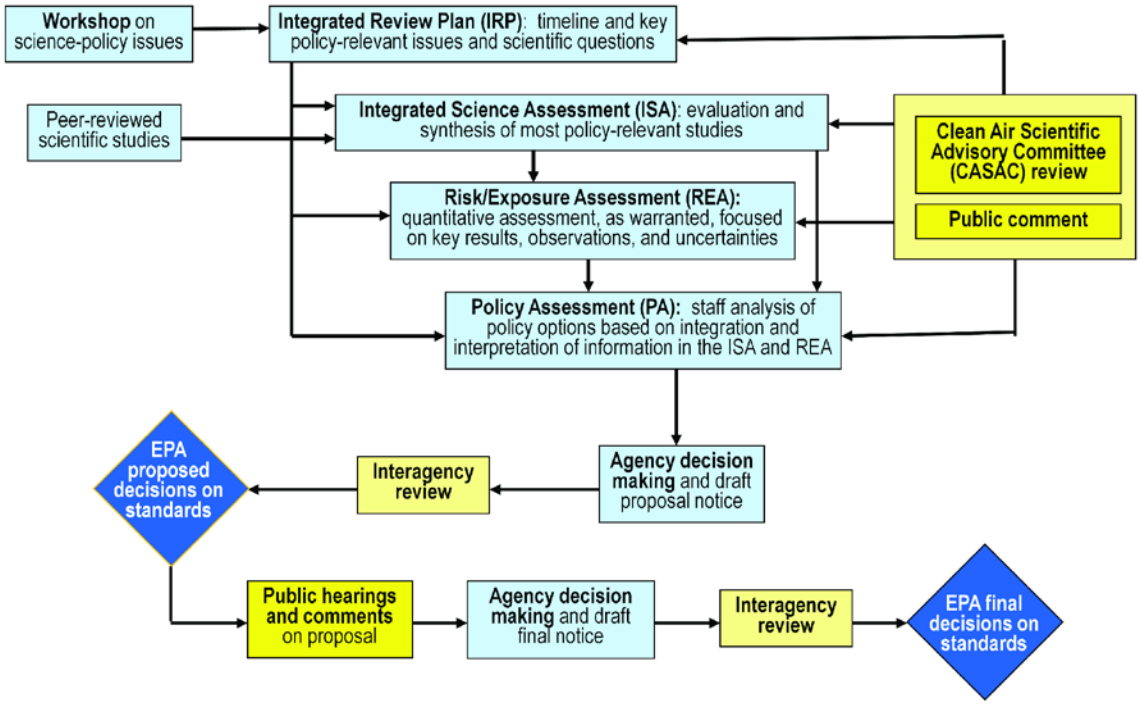

Figure I **Illustration of the key steps in the process of the review of National Ambient Air Quality Standards.**

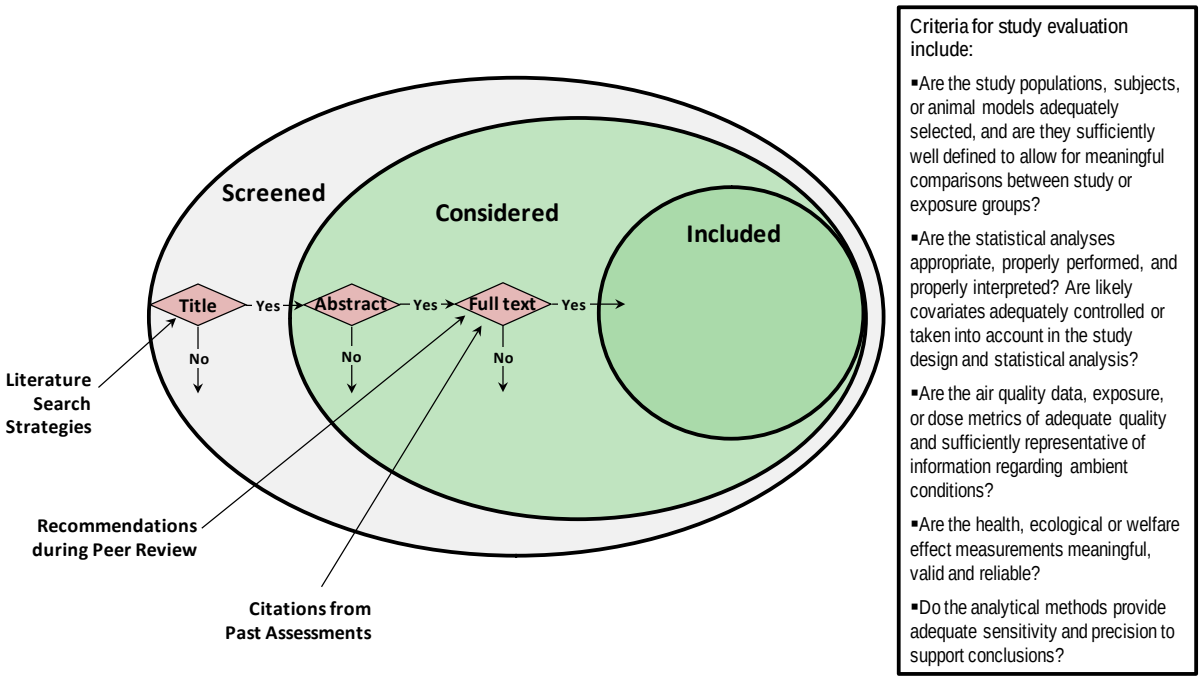

Figure II Illustration of processes for literature search and study selection used for development of ISAs.

Each ISA builds upon the conclusions of previous assessments for the pollutant under review. EPA focuses on peer reviewed literature published following the completion of the previous review and on any new interpretations of previous literature, integrating the results of recent scientific studies with previous findings. Important earlier studies may be discussed in detail to reinforce key concepts and conclusions or for reinterpretation in light of newer data. Earlier studies also are the primary focus in some areas of the document where research efforts have subsided, or if these earlier studies remain the definitive works available in the literature.

Selection of studies for inclusion in the ISA is based on the general scientific quality of the study, and consideration of the extent to which the study is informative and policy-relevant. Policy-relevant and informative studies include those that provide a basis for or describe the relationship between the criteria pollutant and effects, including studies that offer innovation in method or design and studies that reduce uncertainty on critical issues, such as analyses of confounding or effect modification by copollutants or other variables, analyses of concentration-response or dose-response relationships, or analyses related to time between exposure and response. Emphasis is placed on studies that examine effects associated with pollutant concentrations relevant to current population and ecosystem exposures, and particularly those pertaining to concentrations currently found in ambient air. Other studies are included if they contain unique data, such as a previously

unreported effect or MOA for an observed effect, or examine multiple concentrations to elucidate exposure-response relationships. In general, in assessing the scientific quality and relevance of health and welfare effects studies, the following considerations have been taken into account when selecting studies for inclusion in the ISA.

- Are the study populations, subjects, or animal models adequately selected, and are they sufficiently well defined to allow for meaningful comparisons between study or exposure groups?
- Are the statistical analyses appropriate, properly performed, and properly interpreted? Are likely covariates adequately controlled or taken into account in the study design and statistical analysis?
- Are the air quality data, exposure, or dose metrics of adequate quality and sufficiently representative of information regarding ambient conditions?
- Are the health, ecological or welfare effect measurements meaningful, valid and reliable?
- Do the analytical methods provide adequate sensitivity and precision to support conclusions?

Additional considerations are specific to particular disciplines. In selecting epidemiologic studies, EPA considers whether a given study: (1) presents information on associations with short- or long-term pollutant exposures at or near conditions relevant to ambient exposures; (2) addresses potential confounding by other pollutants; (3) assesses potential effect modifiers; (4) evaluates health endpoints and populations not previously extensively researched; and (5) evaluates important methodological issues related to interpretation of the health evidence (e.g., lag or time period between exposure and effects, model specifications, thresholds, mortality displacement).

Considerations for the selection of research evaluating controlled human exposure or animal toxicological studies include a focus on studies conducted using relevant pollutant exposures. For both types of studies, relevant pollutant exposures are considered to be those generally within one or two orders of magnitude of ambient concentrations. Studies in which higher doses were used may also be considered if they provide information relevant to understanding MOA or mechanisms, as noted below.

Evaluation of controlled human exposure studies focuses on those that approximated expected human exposure conditions in terms of concentration and duration. Studies should include control exposures to filtered air, as appropriate. In the selection of controlled human exposure studies, emphasis is placed on studies that: (1) investigate potentially at-risk populations and lifestages such as people with asthma or cardiovascular diseases, children or older adults; (2) address issues such as concentration-

response or time-course of responses; and (3) have sufficient statistical power to assess findings.

Review of the animal toxicological evidence focuses on studies that approximate expected human dose conditions, which vary depending on the dosimetry, toxicokinetics and biological sensitivity of the particular laboratory animal species or strains studied. Emphasis is placed on studies that: (1) investigate animal models of disease that can provide information on populations potentially at increased risk of effects; (2) address issues such as concentration-response or time-course of responses; and (3) have sufficient statistical power to assess findings. Due to resource constraints on exposure duration and numbers of animals tested, animal studies typically utilize high-concentration exposures to acquire data relating to mechanisms and assure a measurable response. Emphasis is placed on studies using doses or concentrations generally within 1-2 orders of magnitude of current levels. Studies with higher concentration exposures or doses are considered to the extent that they provide useful information to inform understanding of interspecies differences between healthy and at-risk human populations. Results from in vitro studies may also be included if they provide mechanistic insight or further support for results demonstrated in vivo.

These criteria provide benchmarks for evaluating various studies and for focusing on the policy-relevant studies in assessing the body of health, ecological and welfare effects evidence. As stated initially, the intent of the ISA is to provide a concise review, synthesis, and evaluation of the most policy-relevant science to serve as a scientific foundation for the review of the NAAQS, not extensive summaries of all health, ecological and welfare effects studies for a pollutant. Of most relevance for inclusion of studies is whether they provide useful qualitative or quantitative information on exposure-effect or exposure-response relationships for effects associated with pollutant exposures at doses or concentrations relevant to ambient conditions that can inform decisions on whether to retain or revise the standards.

The general process for ISA development is illustrated in Figure III. In developing an ISA, EPA reviews and summarizes the evidence from: studies of atmospheric sciences; human exposure, animal toxicological, controlled human exposure and epidemiologic studies; and studies of ecological and welfare effects. In the process of developing the first draft ISA, EPA may convene a peer input meeting in which the scientific content of preliminary draft materials is reviewed to ensure that the ISA is up to date and is focused on the most policy-relevant findings, and to assist EPA with integration of evidence within and across disciplines. EPA integrates the evidence from across scientific disciplines or study types and characterizes the weight of evidence for relationships between the pollutant and various outcomes. The integration of evidence on health, and

ecological or welfare effects, involves collaboration between scientists from various disciplines. As an example, an evaluation of health effects evidence would include the integration of the results from epidemiologic, controlled human exposure, and toxicological studies, and application of the causal framework (described below) to draw conclusions. Integration of results on health or ecological effects that are logically or mechanistically connected (e.g., a spectrum of effects on the respiratory system) informs judgments of causality. Using the causal framework described in the following section, EPA scientists consider aspects such as strength, consistency, coherence, and biological plausibility of the evidence, and develop causality determinations on the nature of the relationships. Causality determinations often entail an iterative process of review and evaluation of the evidence. Two drafts of the ISA are typically released for review by the CASAC and the public, and comments received on the characterization of the science as well as the implementation of the causal framework are carefully considered in revising and completing the final ISA.

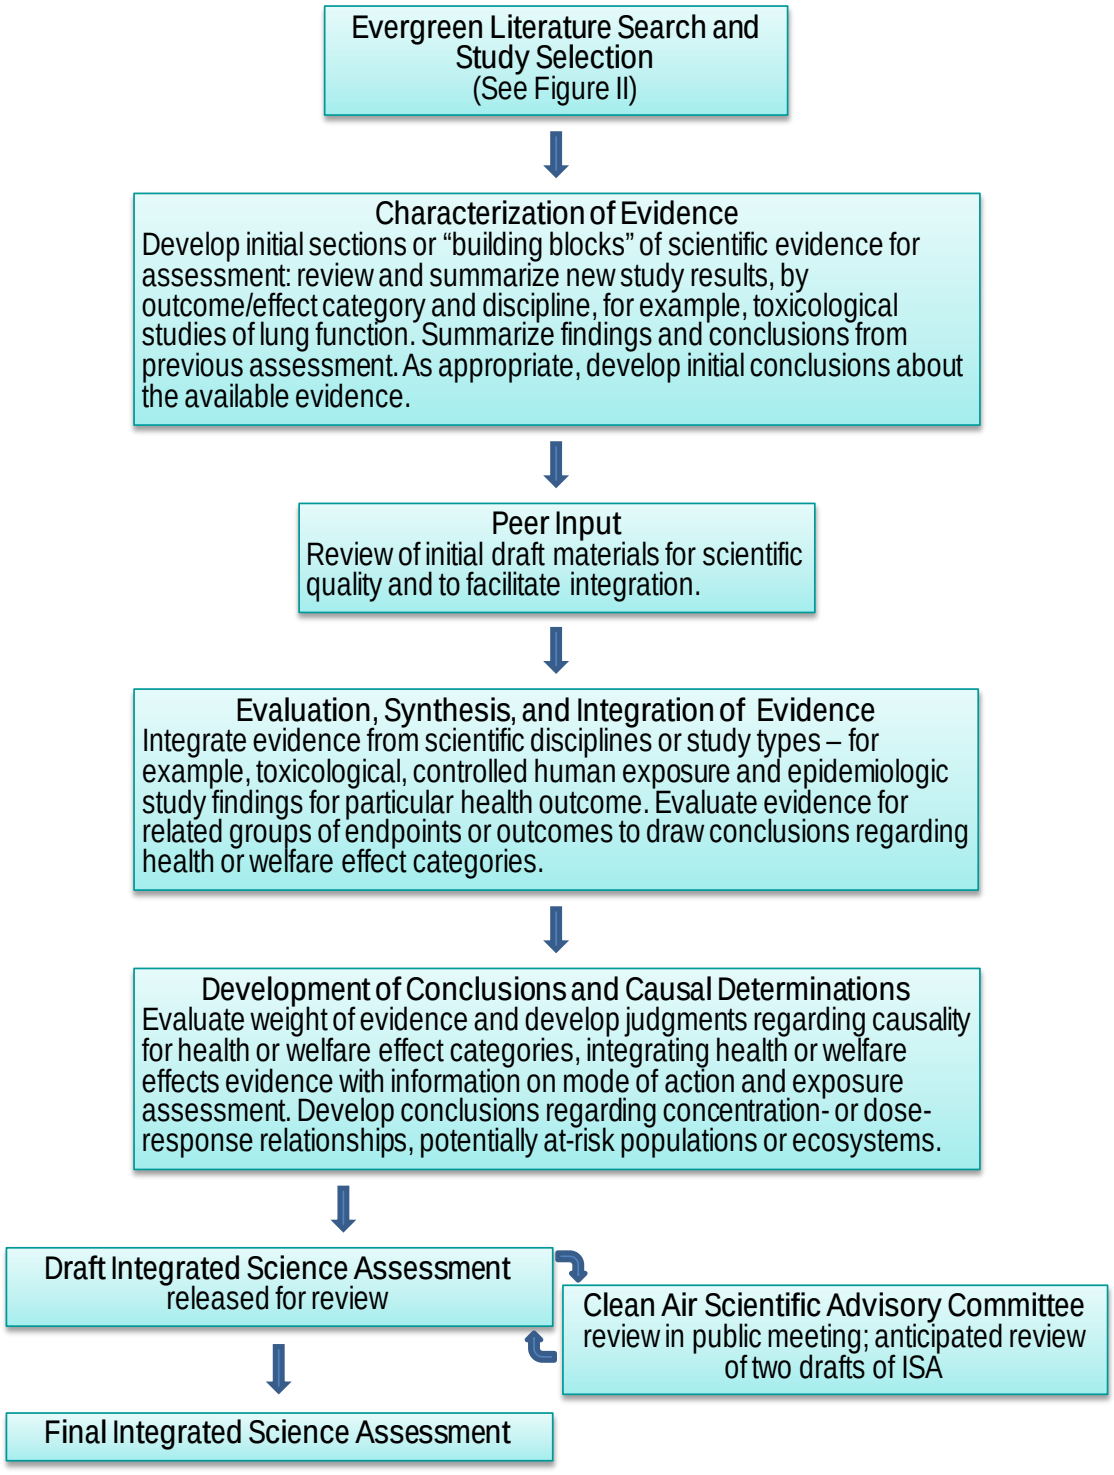

Figure III Characterization of the general process of ISA development.

EPA Framework for Causal Determination

EPA has developed a consistent and transparent basis for integration of scientific evidence and evaluation of the causal nature of air pollution-related health or welfare effects for use in developing ISAs. The framework described below establishes uniform language concerning causality and brings more specificity to the findings. This standardized language was drawn from sources across the federal government and wider scientific community, especially the National Academy of Sciences (NAS) Institute of Medicine (IOM) document, *Improving the Presumptive Disability Decision-Making Process for Veterans* (2008), a comprehensive report on evaluating causality. This framework:

- describes the kinds of scientific evidence used in establishing a general causal relationship between exposure and health effects;
- characterizes the process for integration and evaluation of evidence necessary to reach a conclusion about the existence of a causal relationship;
- identifies issues and approaches related to uncertainty; and
- provides a framework for classifying and characterizing the weight of evidence in support of a general causal relationship.

Approaches to assessing the separate and combined lines of evidence (e.g., epidemiologic, controlled human exposure, and animal toxicological studies) have been formulated by a number of regulatory and science agencies, including the IOM of the NAS (2008), International Agency for Research on Cancer (IARC) (2006b), U.S. EPA (2005c), and Centers for Disease Control and Prevention (CDC) (2004). Causal inference criteria have also been described for ecological effects evidence (U.S. EPA, 1998; Fox, 1991). These formalized approaches offer guidance for assessing causality. The frameworks are similar in nature, although adapted to different purposes, and have proven effective in providing a uniform structure and language for causal determinations.

Evaluating Evidence for Inferring Causation

The 1964 Surgeon General's report defined "cause" as a "significant, effectual relationship between an agent and an associated disorder or disease in the host" (HEW, 1964). More generally, a cause is defined as an agent that brings about an effect or a result. An association is the statistical relationship among variables; alone, however, it is insufficient proof of a causal relationship between an exposure and a health outcome. Unlike an association, a causal claim supports the creation of counterfactual claims, that

is, a claim about what the world would have been like under different or changed circumstances (Samet and Bodurow, 2008).

Many of the health and environmental outcomes reported in these studies have complex etiologies. Diseases such as asthma, coronary heart disease (CHD) or cancer are typically initiated by multiple agents. Outcomes depend on a variety of factors, such as age, genetic susceptibility, nutritional status, immune competence, and social factors (Samet and Bodurow, 2008; Gee and Payne-Sturges, 2004). Effects on ecosystems are often also multifactorial with a complex web of causation. Further, exposure to a combination of agents could cause synergistic or antagonistic effects. Thus, the observed risk may represent the net effect of many actions and counteractions.

Scientific findings incorporate uncertainty. "Uncertainty" can be defined as having limited knowledge to exactly describe an existing state or future outcome, e.g., the lack of knowledge about the correct value for a specific measure or estimate. Uncertainty analysis may be qualitative or quantitative in nature. In many cases, the analysis is qualitative, and can include professional judgment or inferences based on analogy with similar situations. Quantitative uncertainty analysis may include use of simple measures (e.g., ranges) and analytical techniques. Quantitative uncertainty analysis might progress to more complex measures and techniques, if needed for decision support. Various approaches to evaluating uncertainty include classical statistical methods, sensitivity analysis, or probabilistic uncertainty analysis, in order of increasing complexity and data requirements. However, data may not be available for all aspects of an assessment and those data that are available may be of questionable or unknown quality. Ultimately, the assessment is based on a number of assumptions with varying degrees of uncertainty. The ISA generally evaluates uncertainties qualitatively in assessing the evidence from across studies; in some situations quantitative analysis approaches, such as meta-regression, may be used.

Publication bias is a source of uncertainty regarding the magnitude of health risk estimates. It is well understood that studies reporting non-null findings are more likely to be published than reports of null findings. Publication bias can result in overestimation of effect estimate sizes (Ioannidis, 2008). For example, effect estimates from single-city epidemiologic studies have been found to be generally larger than those from multicity studies which is an indication of publication bias in that null or negative single-city results may be reported in a multicity analyses but might not be published independently (Bell et al., 2005).

Consideration of Evidence from Scientific Disciplines

Moving from association to causation involves the elimination of alternative explanations for the association. The ISA focuses on evaluation of the findings from the body of evidence, drawing upon the results of all studies determined to meet the criteria described previously. Causality determinations are based on the evaluation, integration, and synthesis of evidence from across scientific disciplines. The relative importance of different types of evidence varies by pollutant or assessment, as does the availability of different types of evidence for causality determination. Three general types of studies inform consideration of human health effects: controlled human exposure, epidemiologic and toxicological studies. Evidence on ecological or welfare effects may be drawn from a variety of experimental approaches (e.g., greenhouse, laboratory, field) and numerous disciplines (e.g., community ecology, biogeochemistry and paleontological/historical reconstructions).

Direct evidence of a relationship between pollutant exposures and human health effects comes from controlled human exposure studies. Such studies experimentally evaluate the health effects of administered exposures in human volunteers under highly controlled laboratory conditions. Also referred to as human clinical studies, these experiments allow investigators to expose subjects to known concentrations of air pollutants under carefully regulated environmental conditions and activity levels. These studies provide important information on the biological plausibility of associations observed in epidemiologic studies. In some instances, controlled human exposure studies can also be used to characterize concentration-response relationships at pollutant concentrations relevant to ambient conditions. Controlled human exposures are typically conducted using a randomized crossover design, with subjects exposed both to the pollutant and a clean air control. In this way, subjects serve as their own experimental controls, effectively limiting the variance associated with many potential confounders. However, controlled human exposure studies are limited by a number of factors, including small sample size and short exposure time. For example, exposure patterns relevant to understanding real-world exposures, especially long-term exposures, are generally not practical to replicate in a laboratory setting. In addition, although subjects do serve as their own controls, personal exposure to pollutants in the hours and days preceding the controlled exposures may vary significantly between and within individuals. Finally, controlled human exposure studies require investigators to adhere to stringent health criteria for subjects included in the study, and therefore the results often cannot be generalized to an entire population. Although some controlled human exposure studies have included health-compromised individuals such as those with respiratory or cardiovascular disease, these individuals must also be relatively healthy and may not represent the most sensitive individuals in the population. Thus, observed effects in these studies may underestimate

the response in certain populations. In addition, the study design is limited to exposures and endpoints that are not expected to result in severe health outcomes.

Epidemiologic studies provide important information on the associations between health effects and exposure of human populations to ambient air pollution. In epidemiologic or observational studies of humans, the investigator generally does not control exposures or intervene with the study population. Broadly, observational studies can describe associations between exposures and effects. These studies fall into several categories: e.g., cross-sectional, prospective cohort, panel, and time-series studies. "Natural experiments" offer the opportunity to investigate changes in health related to a change in exposure, such as closure of a pollution source.

In evaluating epidemiologic studies, consideration of many study design factors and issues must be taken into account to properly inform their interpretation. One key consideration is evaluation of the potential contribution of the pollutant to a health outcome when it is a component of a complex air pollutant mixture. Reported effect estimates in epidemiologic studies may reflect (1) independent effects on health outcomes; (2) effects of the pollutant acting as an indicator of a copollutant or a complex ambient air pollution mixture; and (3) effects resulting from interactions between that pollutant and copollutants.

In the evaluation of epidemiologic evidence, one important consideration is potential confounding. Confounding is "… a confusion of effects. Specifically, the apparent effect of the exposure of interest is distorted because the effect of an extraneous factor is mistaken for or mixed with the actual exposure effect (which may be null)" (Rothman and Greenland, 1998). One approach to remove spurious associations due to possible confounders is to control for characteristics that may differ between exposed and unexposed persons; this is frequently termed "adjustment." Scientific judgment is needed to evaluate likely sources and extent of confounding, together with consideration of how well the existing constellation of study designs, results, and analyses address the potential for erroneous inferences. A confounder is associated with both the exposure and the effect; for example, confounding can occur between correlated pollutants that are associated with the same effect.

Several statistical methods are available to detect and control for potential confounders; however, none of these methods are being completely satisfactory. Multivariable regression models constitute one tool for estimating the association between exposure and outcome after adjusting for characteristics of participants that might confound the results. The use of multipollutant regression models has been the prevailing approach for controlling potential confounding by copollutants in air pollution health effects studies. Finding the likely causal pollutant from multipollutant regression models is made

difficult by the possibility that one or more air pollutants may be acting as a surrogate for an unmeasured or poorly measured pollutant or for a particular mixture of pollutants. In addition, pollutants may independently exert effects on the same system; for example, several pollutants may be associated with respiratory effect through either the same or different modes of action. The number and degree of diversity of covariates, as well as their relevance to the potential confounders, remain matters of scientific judgment. Despite these limitations, the use of multipollutant models is still the prevailing approach employed in most air pollution epidemiologic studies and provides some insight into the potential for confounding or interaction among pollutants.

Confidence that unmeasured confounders are not producing the findings is increased when multiple studies are conducted in various settings using different subjects or exposures, each of which might eliminate another source of confounding from consideration. For example, multicity studies can provide insight on potential confounding through the use of a consistent method to analyze data from across locations with different levels of copollutants and other covariates. Intervention studies, because of their quasi-experimental nature, can be particularly useful in characterizing causation.

Another important consideration in the evaluation of epidemiologic evidence is effect modification, which occurs when the effect differs between subgroups or strata; for example, effect estimates that vary by age group or potential risk factor. As stated by Rothman and Greenland (1998):

> "Effect-measure modification differs from confounding in several ways. The main difference is that, whereas confounding is a bias that the investigator hopes to prevent or remove from the effect estimate, effect-measure modification is a property of the effect under study … In epidemiologic analysis one tries to eliminate confounding but one tries to detect and estimate effect-measure modification."

When a risk factor is a confounder, it is the true cause of the association observed between the exposure and the outcome; when a risk factor is an effect modifier, it changes the magnitude of the association between the exposure and the outcome in stratified analyses. For example, the presence of a preexisting disease or indicator of low socioeconomic status may act as effect modifiers if they are associated with increased risk of effects related to air pollution exposure. It is often possible to stratify the relationship between health outcome and exposure by one or more of these potential effect modifiers. For variables that modify the association, effect estimates in each stratum will be different from one another and different from the overall estimate, indicating a different exposure-response relationship may exist in populations represented by these variables.

Exposure measurement error, which refers to the uncertainty associated with the exposure metrics used to represent exposure of an individual or population, can be an important contributor to uncertainty in air pollution epidemiologic study results. Exposure error can influence observed epidemiologic associations between ambient pollutant concentrations and health outcomes by biasing effect estimates toward or away from the null and widening confidence intervals around those estimates (Zeger et al., 2000). There are several components that contribute to exposure measurement error in air pollution epidemiologic studies, including the difference between true and measured ambient concentrations, the difference between average personal exposure to ambient pollutants and ambient concentrations at central monitoring sites, and the use of average population exposure rather than individual exposure estimates. Factors that could influence exposure estimates include nonambient sources of exposure, topography of the natural and built environment, meteorology, measurement errors, time-location-activity patterns, and the extent to which ambient pollutants penetrate indoor environments. The importance of exposure error varies with study design and is dependent on the spatial and temporal aspects of the design.

The third main type of health effects evidence, animal toxicological studies, provides information on the pollutant's biological action under controlled and monitored exposure circumstances. Taking into account physiological differences of the experimental species from humans, these studies inform characterization of health effects of concern, exposure-response relationships and MOAs. Further, animal models can inform determinations of at-risk populations. These studies evaluate the effects of exposures to a variety of pollutants in a highly controlled laboratory setting and allow exploration of toxicological pathways or mechanisms by which a pollutant may cause effects. Understanding the biological mechanisms underlying various health outcomes can prove crucial in establishing or negating causality. In the absence of human studies data, extensive, well-conducted animal toxicological studies can support determinations of causality, if the evidence base indicates that similar responses are expected in humans under ambient exposure conditions.

Interpretations of animal toxicological studies are affected by limitations associated with extrapolation between animal and human responses. The differences between humans and other species have to be taken into consideration, including metabolism, hormonal regulation, breathing pattern, and differences in lung structure and anatomy. Also, in spite of a high degree of homology and the existence of a high percentage of orthologous genes across humans and rodents (particularly mice), extrapolation of molecular alterations at the gene level is complicated by species-specific differences in transcriptional regulation. Given these differences, there are uncertainties associated with quantitative extrapolations of observed pollutant-induced pathophysiological alterations

between laboratory animals and humans, as those alterations are under the control of widely varying biochemical, endocrine, and neuronal factors.

For ecological effects assessment, both laboratory and field studies (including field experiments and observational studies) can provide useful data for causality determination. Because conditions can be controlled in laboratory studies, responses may be less variable and smaller differences may be easier to detect. However, the control conditions may limit the range of responses (e.g., animals may not be able to seek alternative food sources) or incompletely reflect pollutant bioavailability, so they may not reflect responses that would occur in the natural environment. In addition, larger-scale processes are difficult to reproduce in the laboratory.

Field observational studies measure biological changes in uncontrolled situations, and describe an association between a disturbance and an ecological effect. Field data can provide important information for assessments of multiple stressors or where site-specific factors significantly influence exposure. They are also often useful for analyses of larger geographic scales and higher levels of biological organization. However, because conditions are not controlled, variability is expected to be higher and differences harder to detect. Field surveys are most useful for linking stressors with effects when stressor and effect levels are measured concurrently. The presence of confounding factors can make it difficult to attribute observed effects to specific stressors.

Some studies are considered ”intermediate” and are categorized as being between laboratory and field are studies. Some use environmental media collected from the field to examine the responses in the laboratory. Others are experiments that are performed in the natural environment while controlling for some, but not all, of the environmental conditions (i.e., mesocosm studies). This type of study in manipulated natural environments can be considered a hybrid between a field experiment and laboratory study since some aspects are performed under controlled conditions but others are not. They make it possible to observe community and/or ecosystem dynamics, and provide strong evidence for causality when combined with findings of studies that have been made under more controlled conditions.

Application of Framework for Causal Determination

In its evaluation of the scientific evidence on health or welfare effects of criteria pollutants, EPA determines the weight of evidence in support of causation and characterizes the strength of any resulting causal classification. EPA also evaluates the quantitative evidence and draws scientific conclusions, to the extent possible, regarding

the concentration-response relationships and the loads to ecosystems, exposures, doses or concentrations, exposure duration, and pattern of exposures at which effects are observed.

Table I Aspects to aid in judging causality.

Aspect	
Consistency of the observed association	An inference of causality is strengthened when a pattern of elevated risks is observed across several independent studies. The reproducibility of findings constitutes one of the strongest arguments for causality. If there are discordant results among investigations, possible reasons such as differences in exposure, confounding factors, and the power of the study are considered.
Coherence	An inference of causality from one line of evidence (e.g., epidemiologic, clinical, or animal studies) may be strengthened by other lines of evidence that support a cause-and-effect interpretation of the association. Evidence on ecological or welfare effects may be drawn from a variety of experimental approaches (e.g., greenhouse, laboratory, and field) and subdisciplines of ecology (e.g., community ecology, biogeochemistry, and paleontological/historical reconstructions). The coherence of evidence from various fields greatly adds to the strength of an inference of causality. In addition, there may be coherence in demonstrating effects across multiple study designs or related health endpoints within one scientific line of evidence.
Biological plausibility.	An inference of causality tends to be strengthened by consistency with data from experimental studies or other sources demonstrating plausible biological mechanisms. A proposed mechanistic linking between an effect and exposure to the agent is an important source of support for causality, especially when data establishing the existence and functioning of those mechanistic links are available.
Biological gradient (exposure-response relationship)	A well-characterized exposure-response relationship (e.g., increasing effects associated with greater exposure) strongly suggests cause and effect, especially when such relationships are also observed for duration of exposure (e.g., increasing effects observed following longer exposure times).
Strength of the observed association	The finding of large, precise risks increases confidence that the association is not likely due to chance, bias, or other factors. However, it is noted that a small magnitude in an effect estimate may represent a substantial effect in a population.
Experimental evidence	Strong evidence for causality can be provided through “natural experiments” when a change in exposure is found to result in a change in occurrence or frequency of health or welfare effects.
Temporal relationship of the observed association	Evidence of a temporal sequence between the introduction of an agent, and appearance of the effect, constitutes another argument in favor of causality.
Specificity of the observed association	Evidence linking a specific outcome to an exposure can provide a strong argument for causation. However, it must be recognized that rarely, if ever, does exposure to a pollutant invariably predict the occurrence of an outcome, and that a given outcome may have multiple causes.
Analogy	Structure activity relationships and information on the agent’s structural analogs can provide insight into whether an association is causal. Similarly, information on mode of action for a chemical, as one of many structural analogs, can inform decisions regarding likely causality.

To aid judgment, various "aspects"[1] of causality have been discussed by many philosophers and scientists. The 1964 Surgeon General's report on tobacco smoking discussed criteria for the evaluation of epidemiologic studies, focusing on consistency, strength, specificity, temporal relationship, and coherence (HEW, 1964). Sir Austin Bradford Hill (Hill, 1965) articulated aspects of causality in epidemiology and public health that have been widely used (Samet and Bodurow, 2008; IARC, 2006b; U.S. EPA, 2005c; CDC, 2004). These aspects (Hill, 1965) have been modified (Table I) for use in causal determinations specific to health and welfare effects for pollutant exposures (U.S. EPA, 2009a).[2] Although these aspects provide a framework for assessing the evidence, they do not lend themselves to being considered in terms of simple formulas or fixed rules of evidence leading to conclusions about causality (Hill, 1965). For example, one cannot simply count the number of studies reporting statistically significant results or statistically nonsignificant results and reach credible conclusions about the relative weight of the evidence and the likelihood of causality. Rather, these aspects are taken into account with the goal of producing an objective appraisal of the evidence, informed by peer and public comment and advice, which includes weighing alternative views on controversial issues. In addition, it is important to note that the aspects in Table I cannot be used as a strict checklist, but rather to determine the weight of the evidence for inferring causality. In particular, not meeting one or more of the principles does not automatically preclude a determination of causality [see discussion in (CDC, 2004)].

Determination of Causality

In the ISA, EPA assesses the body of relevant literature, building upon evidence available during previous NAAQS reviews, to draw conclusions on the causal relationships between relevant pollutant exposures and health or environmental effects. ISAs use a five-level hierarchy that classifies the weight of evidence for causation[3]. In developing this hierarchy, EPA has drawn on the work of previous evaluations, most prominently the IOM's *Improving the Presumptive Disability Decision-Making Process for Veterans* (Samet and Bodurow, 2008), EPA's Guidelines for Carcinogen Risk Assessment (U.S. EPA, 2005c), and the U.S. Surgeon General's smoking report (CDC, 2004). This weight

[1] The "aspects" described by Sir Austin Bradford Hill (Hill, 1965) have become, in the subsequent literature, more commonly described as "criteria." The original term "aspects" is used here to avoid confusion with "criteria" as it is used, with different meaning, in the Clean Air Act.
[2] The Hill aspects were developed for interpretation of epidemiologic results. They have been modified here for use with a broader array of data, i.e., epidemiologic, controlled human exposure, ecological, and animal toxicological studies, as well as in vitro data, and to be more consistent with EPA's Guidelines for Carcinogen Risk Assessment.
[3] The Center for Disease Control (CDC) and IOM frameworks use a four-category hierarchy for the strength of the evidence. A five-level hierarchy is used here to be consistent with the EPA Guidelines for Carcinogen Risk Assessment and to provide a more nuanced set of categories.

of evidence evaluation is based on various lines of evidence from across the health and environmental effects disciplines. These separate judgments are integrated into a qualitative statement about the overall weight of the evidence and causality. The five descriptors for causal determination are described in Table II.

Determination of causality involves the evaluation of evidence for different types of health, ecological or welfare effects associated with short- and long-term exposure periods. In making determinations of causality, evidence is evaluated for major outcome categories or groups of related endpoints (e.g., respiratory effects, vegetation growth), integrating evidence from across disciplines, and evaluating the coherence of evidence across a spectrum of related endpoints to draw conclusions regarding causality. In discussing the causal determination, EPA characterizes the evidence on which the judgment is based, including strength of evidence for individual endpoints within the outcome category or group of related endpoints.

In drawing judgments regarding causality for the criteria air pollutants, the ISA focuses on evidence of effects in the range of relevant pollutant exposures or doses, and not on determination of causality at any dose. Emphasis is placed on evidence of effects at doses (e.g., blood Pb concentration) or exposures (e.g., air concentrations) that are relevant to, or somewhat above, those currently experienced by the population. The extent to which studies of higher concentrations are considered varies by pollutant and major outcome category, but generally includes those with doses or exposures in the range of one to two orders of magnitude above current or ambient conditions. Studies that use higher doses or exposures may also be considered to the extent that they provide useful information to inform understanding of mode of action, interspecies differences, or factors that may increase risk of effects for a population. Thus, a causality determination is based on weight of evidence evaluation for health, ecological or welfare effects, focusing on the evidence from exposures or doses generally ranging from current levels to one or two orders of magnitude above current levels.

In addition, EPA evaluates evidence relevant to understand the quantitative relationships between pollutant exposures and health, ecological or welfare effects. This includes evaluation of the form of concentration-response or dose-response relationships and, to the extent possible, drawing conclusions on the levels at which effects are observed. The ISA also draws scientific conclusions regarding important exposure conditions for effects and populations that may be at greater risk for effects, as described in the following section.

Table II Weight of evidence for causal determination.

	Health Effects	Ecological and Welfare Effects
Causal relationship	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures (i.e., doses or exposures generally within one to two orders of magnitude of current levels). That is, the pollutant has been shown to result in health effects in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. For example: a) controlled human exposure studies that demonstrate consistent effects; or b) observational studies that cannot be explained by plausible alternatives or are supported by other lines of evidence (e.g., animal studies or mode of action information). Evidence includes multiple high-quality studies	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures i.e., doses or exposures generally within one to two orders of magnitude of current levels). That is, the pollutant has been shown to result in effects in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. Controlled exposure studies (laboratory or small- to medium-scale field studies) provide the strongest evidence for causality, but the scope of inference may be limited. Generally, determination is based on multiple studies conducted by multiple research groups, and evidence that is considered sufficient to infer a causal relationship is usually obtained from the joint consideration of many lines of evidence that reinforce each other.
Likely to be a causal relationship	Evidence is sufficient to conclude that a causal relationship is likely to exist with relevant pollutant exposures, but important uncertainties remain. That is, the pollutant has been shown to result in health effects in studies in which chance and bias can be ruled out with reasonable confidence but potential issues remain. For example: a) observational studies show an association, but copollutant exposures are difficult to address and/or other lines of evidence (controlled human exposure, animal, or mode of action information) are limited or inconsistent; or b) animal toxicological evidence from multiple studies from different laboratories that demonstrate effects, but limited or no human data are available. Evidence generally includes multiple high-quality studies.	Evidence is sufficient to conclude that there is a likely causal association with relevant pollutant exposures. That is, an association has been observed between the pollutant and the outcome in studies in which chance, bias, and confounding are minimized, but uncertainties remain. For example, field studies show a relationship, but suspected interacting factors cannot be controlled, and other lines of evidence are limited or inconsistent. Generally, determination is based on multiple studies in multiple research groups.
Suggestive of a causal relationship	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but is limited. For example, (a) at least one high-quality epidemiologic study shows an association with a given health outcome but the results of other studies are inconsistent; or (b) a well-conducted toxicological study, such as those conducted in the National Toxicology Program (NTP), shows effects in animal species,	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but chance, bias and confounding cannot be ruled out. For example, at least one high-quality study shows an effect, but the results of other studies are inconsistent.
Inadequate to infer a causal relationship	Evidence is inadequate to determine that a causal relationship exists with relevant pollutant exposures. The available studies are of insufficient quantity, quality, consistency, or statistical power to permit a conclusion regarding the presence or absence of an effect.	The available studies are of insufficient quality, consistency, or statistical power to permit a conclusion regarding the presence or absence of an effect.
Not likely to be a causal relationship	Evidence is suggestive of no causal relationship with relevant pollutant exposures. Several adequate studies, covering the full range of levels of exposure that human beings are known to encounter and considering at-risk populations, are mutually consistent in not showing an effect at any level of exposure.	Several adequate studies, examining relationships with relevant exposures, are consistent in failing to show an effect at any level of exposure.

Quantitative Relationships: Effects on Human Populations

Once a determination is made regarding the causal relationship between the pollutant and outcome category, important questions regarding quantitative relationships include:

- What is the concentration-response, exposure-response, or dose-response relationship in the human population?
- What is the interrelationship between incidence and severity of effect?
- What exposure conditions (dose or exposure, duration and pattern) are important?
- What populations and lifestages appear to be differentially affected (i.e., more at risk of experiencing effects)?

In order to address these questions, the entirety of quantitative evidence is evaluated to characterize pollutant concentrations and exposure durations at which effects were observed for exposed populations, including populations and lifestages potentially at increased risk. To accomplish this, evidence is considered from multiple and diverse types of studies, and a study or set of studies that best approximates the concentration-response relationships between health outcomes and the pollutant may be identified. Controlled human exposure studies provide the most direct and quantifiable exposure-response data on the human health effects of pollutant exposures. To the extent available, the ISA evaluates results from across epidemiologic studies that characterize the form of relationships between the pollutant and health outcomes and draws conclusions on the shape of these relationships. Animal data may also inform evaluation of concentration-response relationships, particularly relative to MOAs and characteristics of at-risk populations.

An important consideration in characterizing the public health impacts associated with exposure to a pollutant is whether the concentration-response relationship is linear across the range of concentrations or if nonlinear relationships exist along any part of this range. The shape of the concentration-response curve at and below the level of the current standards is of particular interest. Various sources of variability and uncertainty, such as low data density in the lower concentration range, possible influence of exposure measurement error, and variability between individuals in susceptibility to air pollution health effects, tend to smooth and “linearize” the concentration-response function, and thus can obscure the existence of a threshold or nonlinear relationship. Since individual thresholds vary from person to person due to individual differences such as genetic level susceptibility or preexisting disease conditions (and even can vary from one time to another for a given person), it can be difficult to demonstrate that a threshold exists in a population study. These sources of variability and uncertainty may explain why the

available human data at ambient concentrations for some environmental pollutants (e.g., particulate matter [PM], O_3, lead [Pb], environmental tobacco smoke [ETS], radiation) do not exhibit thresholds for cancer or noncancer health effects, even though likely mechanisms include nonlinear processes for some key events. These attributes of human population dose-response relationships have been extensively discussed in the broader epidemiologic literature (Rothman and Greenland, 1998).

Finally, identification of the population groups or lifestages that may be at greater risk of health effects from air pollutant exposures contributes to an understanding of the public health impact of pollutant exposures. In the ISA, the term "at-risk population" is used to encompass populations or lifestages that have a greater likelihood of experiencing health effects related to exposure to an air pollutant due to a variety of factors; other terms used in the literature include susceptible, vulnerable, and sensitive. These factors may be intrinsic, such as genetic or developmental factors, race, gender, lifestage, or the presence of preexisting diseases, or they may be extrinsic, such as socioeconomic status (SES), activity pattern and exercise level, reduced access to health care, low educational attainment, or increased pollutant exposures (e.g., near roadways). Epidemiologic studies can help identify populations potentially at increased risk of effects by evaluating health responses in the study population. Examples include testing for interactions or effect modification by factors such as gender, age group, or health status. Experimental studies using animal models of susceptibility or disease can also inform the extent to which health risks are likely greater in specific population groups.

Quantitative Relationships: Effects on Ecosystems or Public Welfare

Key questions for understanding the quantitative relationships between exposure (or concentration or deposition) to a pollutant and risk to ecosystems or the public welfare include:

- What elements of the ecosystem (e.g., types, regions, taxonomic groups, populations, functions, etc.) appear to be affected, or are more sensitive to effects? Are there differences between locations or materials in welfare effects responses, such as impaired visibility or materials damage?
- Under what exposure conditions (amount deposited or concentration, duration and pattern) are effects seen?
- What is the shape of the concentration-response or exposure-response relationship?

Evaluations of causality generally consider the probability of quantitative changes in ecological and welfare effects in response to exposure. A challenge to the quantification

of exposure-response relationships for ecological effects is the great regional and local spatial variability, as well as temporal variability, in ecosystems. Thus, exposure-response relationships are often determined for a specific ecological system and scale, rather than at the national or even regional scale. Quantitative relationships therefore are estimated site by site and may differ greatly between ecosystems.

Concepts in Evaluating Adversity of Health Effects

In evaluating health evidence, a number of factors can be considered in delineating between adverse and nonadverse health effects resulting from exposure to air pollution. Some health outcomes, such as hospitalization for respiratory or cardiovascular diseases, are clearly considered adverse. It is more difficult to determine the extent of change that constitutes adversity in more subtle health measures. These include a wide variety of responses, such as alterations in markers of inflammation or oxidative stress, changes in pulmonary function or heart rate variability, or alterations in neurocognitive function measures. The challenge is determining the magnitude of change in these measures when there is no clear point at which a change becomes adverse. The extent to which a change in health measure constitutes an adverse health effect may vary between populations. Some changes that may not be considered adverse in healthy individuals would be potentially adverse in more at-risk individuals.

The extent to which changes in lung function are adverse has been discussed by the American Thoracic Society (ATS) in an official statement titled *What Constitutes an Adverse Health Effect of Air Pollution?* (ATS, 2000). An air pollution-induced shift in the population distribution of a given risk factor for a health outcome was viewed as adverse, even though it may not increase the risk of any one individual to an unacceptable level. For example, a population of asthmatics could have a distribution of lung function such that no identifiable individual has a level associated with significant impairment. Exposure to air pollution could shift the distribution such that no identifiable individual experiences clinically relevant effects. This shift toward decreased lung function, however, would be considered adverse because individuals within the population would have diminished reserve function and therefore would be at increased risk to further environmental insult. The committee also observed that elevations of biomarkers, such as cell number and types, cytokines and reactive oxygen species, may signal risk for ongoing injury and clinical effects or may simply indicate transient responses that can provide insights into mechanisms of injury, thus illustrating the lack of clear boundaries that separate adverse from nonadverse effects.

The more subtle health outcomes may be connected mechanistically to health events that are clearly adverse. For example, air pollution may affect markers of transient myocardial

ischemia such as ST-segment abnormalities or onset of exertional angina. These effects may not be apparent to the individual, yet may still increase the risk of a number of cardiac events, including myocardial infarction and sudden death. Thus, small changes in physiological measures may not appear to be clearly adverse when considered alone, but may be a part of a coherent and biologically plausible chain of related health outcomes that range up to responses that are very clearly adverse, such as hospitalization or mortality.

Concepts in Evaluating Adversity of Ecological Effects

Adversity of ecological effects can be understood in terms ranging in biological level of organization; from the cellular level to the individual organism and to the population, community, and ecosystem levels. In the context of ecology, a population is a group of individuals of the same species, and a community is an assemblage of populations of different species interacting with one another that inhabit an area. An ecosystem is the interactive system formed from all living organisms and their abiotic (physical and chemical) environment within a given area (IPCC, 2007). The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus, the extent of an ecosystem may range from very small spatial scales to, ultimately, the entire Earth (IPCC, 2007).

Effects on an individual organism are generally not considered to be adverse to public welfare. However if effects occur to enough individuals within a population, then communities and ecosystems may be disrupted. Changes to populations, communities, and ecosystems can in turn result in an alteration of ecosystem processes. Ecosystem processes are defined as the metabolic functions of ecosystems including energy flow, elemental cycling, and the production, consumption and decomposition of organic matter (U.S. EPA, 2002a). Growth, reproduction, and mortality are species-level endpoints that can be clearly linked to community and ecosystem effects and are considered to be adverse when negatively affected. Other endpoints such as changes in behavior and physiological stress can decrease ecological fitness of an organism, but are harder to link unequivocally to effects at the population, community, and ecosystem level. The degree to which pollutant exposure is considered adverse may also depend on the location and its intended use (i.e., city park, commercial, cropland). Support for consideration of adversity beyond the species level by making explicit the linkages between stress-related effects at the species and effects at the ecosystem level is found in *A Framework for Assessing and Reporting on Ecological Condition: an SAB report* (U.S. EPA, 2002a). Additionally, the National Acid Precipitation Assessment Program (NAPAP, 1991) uses the following working definition of “adverse ecological effects” in the preparation of reports to Congress mandated by the Clean Air Act: “any injury (i.e., loss of chemical or

physical quality or viability) to any ecological or ecosystem component, up to and including at the regional level, over both long and short terms."

On a broader scale, ecosystem services may provide indicators for ecological impacts. Ecosystem services are the benefits that people obtain from ecosystems (UNEP, 2003). According to the Millennium Ecosystem Assessment, ecosystem services include: "provisioning services such as food and water; regulating services such as regulation of floods, drought, land degradation, and disease; supporting services such as soil formation and nutrient cycling; and cultural services such as recreational, spiritual, religious and other nonmaterial benefits." For example, a more subtle ecological effect of pollution exposure may result in a clearly adverse impact on ecosystem services if it results in a population decline in a species that is recreationally or culturally important.

Legislative and Historical Background

Legislative Requirements for the NAAQS Review

Two sections of the Clean Air Act (CAA) govern the establishment and revision of the NAAQS. Section 108 (42:U.S.C.:7408) directs the Administrator to identify and list certain air pollutants and then to issue air quality criteria for those pollutants. The Administrator is to list those air pollutants that in her "… judgment, cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare; …" and, "… the presence of which in the ambient air results from numerous or diverse mobile or stationary sources;" and, "… for which … [the Administrator] plans to issue air quality criteria…. ." Air quality criteria are intended to "accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of [a] pollutant in the ambient air …" (42:U.S.C.:7408([b]). Section 109 (42:U.S.C.:7409) directs the Administrator to propose and promulgate "primary" and "secondary" NAAQS for pollutants for which air quality criteria are issued. Section 109(b)(1) defines a primary standard as one "…the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health." The legislative history of Section 109 indicates that a primary standard is to be set at "… the maximum permissible ambient air level … which will protect the health of any [sensitive] group of the population," and that for this purpose "… reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group…" (S. Rep. No. 91:1196, 91st Cong., 2d Sess. 10 [1970]). A secondary standard, as defined in Section 109(b)(2), must "… specify a level of air quality the attainment and maintenance of which, in the judgment of the Administrator, based on such criteria, is requisite to protect the public welfare from any known or anticipated adverse effects associated with the presence of [the] pollutant in the ambient air." Welfare effects (as defined in Section 302(h); 42:U.S.C.:7602[h]) include, but are not limited to, "… effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being."

The requirement that primary standards provide an adequate margin of safety was intended to address uncertainties associated with inconclusive scientific and technical information available at the time of standard setting. It was also intended to provide a reasonable degree of protection against hazards that research has not yet identified (*Lead Industries Association v. EPA,* 647:F.2d:1130-1154 [D.C.Cir 1980]; *American Petroleum*

Institute v. Costle, 665:F.2d:1176-1186 [D.C.Cir. 1981]; *American Farm Bureau Federation v. EPA*, 559:F.3d:512-533 [D.C. Cir. 2009]; *Association of Battery Recyclers v. EPA*, 604:F.3d:613, 617-618 [D.C. Cir. 2010]). Both kinds of uncertainties are components of the risk associated with pollution at levels below those at which human health effects can be said to occur with reasonable scientific certainty. Thus, in selecting primary standards that provide an adequate margin of safety, the Administrator is seeking not only to prevent pollution levels that have been demonstrated to be harmful but also to prevent lower pollutant levels that may pose an unacceptable risk of harm, even if the risk is not precisely identified as to nature or degree. The CAA does not require the Administrator to establish a primary NAAQS at a zero-risk level or at background concentration levels (*Lead Industries v. EPA*, [647:F.2d:at 1156 n.51]), but rather at a level that reduces risk sufficiently so as to protect public health with an adequate margin of safety.

In addressing the requirement for an adequate margin of safety, the EPA considers such factors as the nature and severity of the health effects involved, the size of sensitive population(s) at risk, and the kind and degree of the uncertainties that must be addressed. The selection of any particular approach to providing an adequate margin of safety is a policy choice left specifically to the Administrator's judgment (*Lead Industries Association v. EPA*, [647:F.2d:1161-1162]; *Whitman v. American Trucking Associations*, [531:U.S.:457-495 (2001)]).

In setting standards that are "requisite" to protect public health and welfare as provided in Section 109(b), EPA's task is to establish standards that are neither more nor less stringent than necessary for these purposes. In so doing, EPA may not consider the costs of implementing the standards (see generally, *Whitman v. American Trucking Associations*, [531:U.S.:457, 465-472, 475-476 (2001)]). Likewise, "… [a]ttainability and technological feasibility are not relevant considerations in the promulgation of national ambient air quality standards." (*American Petroleum Institute v. Costle*, [665:F.2d:1185]).

Section 109(d)(1) requires that "not later than December 31, 1980, and at 5-year intervals thereafter, the Administrator shall complete a thorough review of the criteria published under Section 108 and the national ambient air quality standards … and shall make such revisions in such criteria and standards and promulgate such new standards as may be appropriate … ." Section 109(d)(2) requires that an independent scientific review committee "shall complete a review of the criteria … and the national primary and secondary ambient air quality standards … and shall recommend to the Administrator any new … standards and revisions of existing criteria and standards as may be appropriate … ." Since the early 1980's, this independent review function has been performed by the Clean Air Scientific Advisory Committee (CASAC).

History of the NAAQS for Pb

Unlike pollutants such as PM and carbon monoxide (CO), air quality criteria had not been issued for Pb as of the enactment of the Clean Air Act of 1970, which first set forth the requirement to set national ambient air quality standards for criteria pollutants. EPA did not intend to issue air quality criteria for lead, and accordingly had not listed lead under Section 108. EPA had determined to control lead air pollution through regulations to phase-out use of lead additives in gasoline and EPA viewed those controls, and possibly additional federal controls, as the best approach to controlling lead emissions (See 41 FR 14921 (April 8, 1976). However, the decision not to list lead under Section 108 was challenged by environmental and public health groups and the U.S. District Court for the Southern District of New York concluded that EPA was required to list lead under Section 108. (*Natural Resources Defense Council v. EPA*, 411 F. Supp. 864 [S.D. N.Y. 1976], aff'd, 545 F.2d 320 [2d Cir. 1978]).

Accordingly, on April 8, 1976, EPA published a notice that Pb had been listed under Section 108 as a criteria pollutant (41 FR 14921) and on October 5, 1978, EPA promulgated primary and secondary NAAQS for Pb under Section 109 of the Act (43 FR 46246). Both primary and secondary standards were set at a level of 1.5 micrograms per cubic meter ($\mu g/m^3$), measured as Pb in total suspended particles (Pb-TSP), not to be exceeded by the maximum arithmetic mean concentration averaged over a calendar quarter. These standards were based on the 1977 Pb Air Quality Criteria for Lead Document (AQCD) (U.S. EPA, 1977).

The first review of the Pb standards was initiated in the mid-1980s. The scientific assessment for that review is described in the 1986 Pb AQCD (U.S. EPA, 1986a), the associated Addendum (U.S. EPA, 1986c) and the 1990 Supplement (U.S. EPA, 1990a). As part of the review, the Agency designed and performed human exposure and health risk analyses (U.S. EPA, 1989), the results of which were presented in a 1990 Staff Paper

(U.S. EPA, 1990c). Based on the scientific assessment and the human exposure and health risk analyses, the 1990 Staff Paper presented recommendations for consideration by the Administrator (U.S. EPA, 1990c). After consideration of the documents developed during the review and the significantly changed circumstances since Pb was listed in 1976, the Agency did not propose any revisions to the 1978 Pb NAAQS. In a parallel effort, the Agency developed the broad, multi-program, multimedia, integrated U.S. Strategy for Reducing Lead Exposure (U.S. EPA, 1991). As part of implementing this strategy, the Agency focused efforts primarily on regulatory and remedial clean-up actions aimed at reducing Pb exposures from a variety of non-air sources judged to pose more extensive public health risks to U.S. populations, as well as on actions to reduce Pb emissions to air, such as bringing more areas into compliance with the existing Pb NAAQS (U.S. EPA, 1991).

The most recent review of the Pb air quality criteria and standards was initiated in November, 2004 (69 FR 64926) and the Agency's plans for preparation of the *Air Quality Criteria Document* (AQCD) and conduct of the NAAQS review were contained in two documents: *Project Work Plan for Revised Air Quality Criteria for Lead* (U.S. EPA, 2005e); and *Plan for Review of the National Ambient Air Quality Standards for Lead* (U.S. EPA, 2006e). The schedule for completion of this review was governed by a judicial order in *Missouri Coalition for the Environment v. EPA* (No. 4:04CV00660 ERW, Sept. 14, 2005; and amended on April 29, 2008 and July 1, 2008), which specified a schedule for the review of duration substantially shorter than five years.

The scientific assessment for the review is described in the 2006 *Air Quality Criteria for Lead* [2006 Pb AQCD; (U.S. EPA, 2006b)], multiple drafts of which received review by CASAC and the public. EPA also conducted human exposure and health risk assessments and a pilot ecological risk assessment for the review, after consultation with CASAC and receiving public comment on a draft analysis plan (U.S. EPA, 2006d). Drafts of these quantitative assessments were reviewed by CASAC and the public. The pilot ecological risk assessment was released in December 2006 (ICF, 2006) and the final health risk assessment report was released in November 2007 (U.S. EPA, 2007g). The policy assessment based on both of these assessments, air quality analyses and key evidence from the AQCD was presented in the Staff Paper (U.S. EPA, 2006f), a draft of which also received CASAC and public review. The final Staff Paper presented OAQPS staff's evaluation of the public health and welfare policy implications of the key studies and scientific information contained in the 2006 Pb AQCD and presented and interpreted results from the quantitative risk/exposure analyses conducted for this review. Based on this evaluation, the Staff Paper presented OAQPS staff recommendations that the Administrator give consideration to substantially revising the primary and secondary standards to a range of levels at or below 0.2 $\mu g/m^3$.

Immediately subsequent to completion of the Staff Paper, EPA issued an advance notice of proposed rulemaking (ANPR) that was signed by the Administrator on December 5, 2007 (72 FR 71488).[1] CASAC provided advice and recommendations to the Administrator with regard to the Pb NAAQS based on its review of the ANPR and the previously released final Staff Paper and risk assessment reports. The proposed decision on revisions to the Pb NAAQS was signed on May 1, 2008 and published in the Federal Register on May 20, 2008 (73 FR 29184). Members of the public provided both written and, at two public hearings, oral comments and the CASAC Pb Panel also provided advice and recommendations to the Administrator based on its review of the proposal notice. The final decision on revisions to the Pb NAAQS was signed on October 15, 2008 and published in the Federal Register on November 12, 2008 (73 FR 66964).

The November 2008 notice described EPA's decision to revise the primary and secondary NAAQS for Pb from a level of 1.5 $\mu g/m^3$ to a level of 0.15 $\mu g/m^3$. EPA's decision on the level for the primary standard was based on the much-expanded health effects evidence on neurocognitive effects of Pb in children. The level of 0.15 $\mu g/m^3$ was established to protect against air Pb-related health effects, including intelligence quotient (IQ) decrements in the most highly exposed children, those exposed at the level of the standard. Results of the quantitative risk assessment were judged supportive of the evidence-based framework estimates. The averaging time was revised to a rolling three-month period with a maximum (not-to-be-exceeded) form, evaluated over a three-year period. As compared to the previous averaging time of calendar quarter, this revision was considered to be more scientifically appropriate and more health protective. The rolling average gives equal weight to all three-month periods, and the new calculation method gives equal weight to each month within each three-month period. Further, the rolling average yields 12 three-month averages each year to be compared to the NAAQS versus four averages in each year for the block calendar quarters pertaining to the previous standard. The indicator of Pb-TSP was retained, reflecting the evidence that Pb particles of all sizes pose health risks. The secondary standard was revised to be identical in all respects to the revised primary standards.[2]

Revisions to the NAAQS were accompanied by revisions to the data handling procedures, the treatment of exceptional events, and the ambient air monitoring and reporting requirements, as well as emissions inventory reporting requirements.[3] One

[1] The ANPR was one of the features of the revised NAAQS review process that EPA instituted in 2006. In 2009, this component of the process was replaced by reinstatement of the OAQPS policy assessment (previously termed the Staff Paper).
[2] The 2008 NAAQS for Pb are specified at 40 CFR 50.16.
[3] The 2008 federal regulatory measurement methods for Pb are specified in 40 CFR 50, Appendix G and 40 CFR part 53. Consideration of ambient air measurements with regard to judging attainment of the standards is specified in 40 CFR 50, Appendix R. The Pb monitoring network requirements are specified in 40 CFR 58, Appendix D, section

aspect of the new data handling requirements is the allowance for the use of Pb-PM_{10} monitoring for Pb NAAQS attainment purposes in certain limited circumstances at non-source-oriented sites. The monitoring network requirements resulted in a substantial number of new monitors being required as of January 2010, Subsequent to the 2008 rulemaking, additional revisions were made to the monitoring network requirements, which required additional monitors as of December 2011; the complete current requirements are described in Section 3.4.

On February 26, 2010 (75 FR 8934), EPA formally initiated its current review of the air quality criteria for Pb, requesting the submission of recent scientific information on specified topics. Soon after, a science policy workshop was held to identify key policy issues and questions to frame the review of the Pb NAAQS (75 FR 20843). Drawing from the workshop discussions, a draft IRP [*Integrated Review Plan for the National Ambient Air Quality Standards for Lead* (U.S. EPA, 2011d)], was developed and made available in late March, 2011 for public comment and consultation with CASAC and was discussed by the CASAC via a publicly accessible teleconference consultation on May 5, 2011 (76 FR 20347, 76 FR 21346). The final IRP (U.S. EPA, 2011c) was released in November, 2011 (76 FR 76972).

As part of the science assessment phase of the current review, EPA held a workshop in December 2010 (75 FR 69078) to discuss, with invited scientific experts, preliminary draft materials prepared during the ongoing development of the Pb ISA. The first external review draft *ISA for Lead* was released on May 6, 2011 (U.S. EPA, 2011e). The CASAC Pb Review Panel met at a public meeting on July 20, 2011 to review the draft ISA (76 FR 36120). Subsequently, on December 9, 2011, the CASAC panel provided a consensus letter for their review to the Administrator of the EPA (Frey and Samet, 2011). The second external review draft *ISA for Lead*, (U.S. EPA, 2012) was discussed at a public meeting of the CASAC Pb Review Panel on April 10, 2012. The third external review draft ISA for Lead will be discussed at a public meeting of the CASAC Pb review Panel, and timely public comments received will be provided to the CASAC panel. A future Federal Register notice will inform the public of the exact date and time of that CASAC meeting.

4.5. Guidance on the approach for implementation of the new standards was described in the Federal Register notices for the proposed and final rules (73 FR 29184; 73 FR 66964).

1 EXECUTIVE SUMMARY

1.1 Introduction

This Integrated Science Assessment (ISA) is a synthesis and evaluation of the most policy-relevant science that forms the scientific foundation for the review of the primary (health-based) and secondary (welfare-based) national ambient air quality standard (NAAQS) for Lead (Pb). In 2008, the levels of the primary and secondary NAAQS for Pb were lowered ten-fold, from the 1978 level of 1.5 $\mu g/m^3$, to a level of 0.15 $\mu g/m^3$. The averaging time was revised to a rolling three-month period with a maximum (not-to-be-exceeded) form, evaluated over a three-year period. EPA's decision on the level for the revised primary standard in 2008 was based on the substantive increase in the evidence on neurocognitive effects of Pb in children. The revised standard was established to protect against air Pb-related health effects, including intelligence quotient (IQ) loss, in the most highly exposed children.

The U.S. Environmental Protection Agency (EPA) has a systematic process for evaluating the scientific evidence and drawing conclusions and judgments regarding the causal association of air pollution with health and environmental effects. The ISA process includes literature search strategies, criteria for selecting and evaluating studies, approaches for evaluating the weight of the evidence, and a framework for making causality determinations. The ISA uses this five-level hierarchy that classifies the weight of evidence for causation:

- Causal relationship
- Likely to be a causal relationship
- Suggestive of a causal relationship
- Inadequate to infer a causal relationship
- Not likely to be a causal relationship

The process and causality framework are described in more detail in the Preamble to the ISA. Considerations that are specific to the causal determinations drawn for the health and ecological effects of Pb are described in Section 2.1 of the document.

1.2 Sources, Fate and Transport of Lead (Pb) in the Environment, and the Resulting Human Exposure and Dose

Emissions of Pb to ambient air have declined by more than two orders of magnitude over the period 1970 to 2008 following the ban on alkyl-Pb additives for on-road gasoline and tightened industrial emission standards. Emissions in the U.S. were estimated to be 964 tons in 2008, a small fraction of the total Pb used in production. More than half of these emissions were from piston-engine aircraft. Other important sources of ambient air Pb, beginning with the next largest, include metals processing, fossil fuel combustion, other industrial sources, and roadway-related sources.

During the same period that saw the dramatic decrease in Pb emissions, ambient air Pb concentrations[1] also declined. The median annual concentration in 2010, 0.03 micrograms per cubic meter ($\mu g/m^3$), was approximately thirty times lower than it was in 1980. The sharpest drop in median Pb concentration occurred from 1980-1990; concentrations continued to decline up to 2010. Specific levels near Pb sources as well as away from Pb sources have also shown a sharp decrease (Section 2.2.2).

Atmospheric deposition has led to measurable Pb concentrations in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with the highest concentrations near Pb sources, such as smelters. After the phase-out of Pb from on-road gasoline and declining industrial emissions, Pb concentrations have decreased considerably in rain, snowpack, and surface waters. Pb is retained in soils and sediments, where it provides a historical record of deposition and associated concentrations. The national average Pb concentration in soil was 18.9 milligrams of Pb per kilogram (mg Pb/kg), measured in over 1,300 non-urban, generally vegetated sampling locations. The national median fresh surface water Pb concentration was 0.5 micrograms per liter (µg/L) (Section 2.2.3). In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth; sediment profiles indicate peak Pb concentrations between 1960 and 1980 (when leaded gasoline was at peak use).

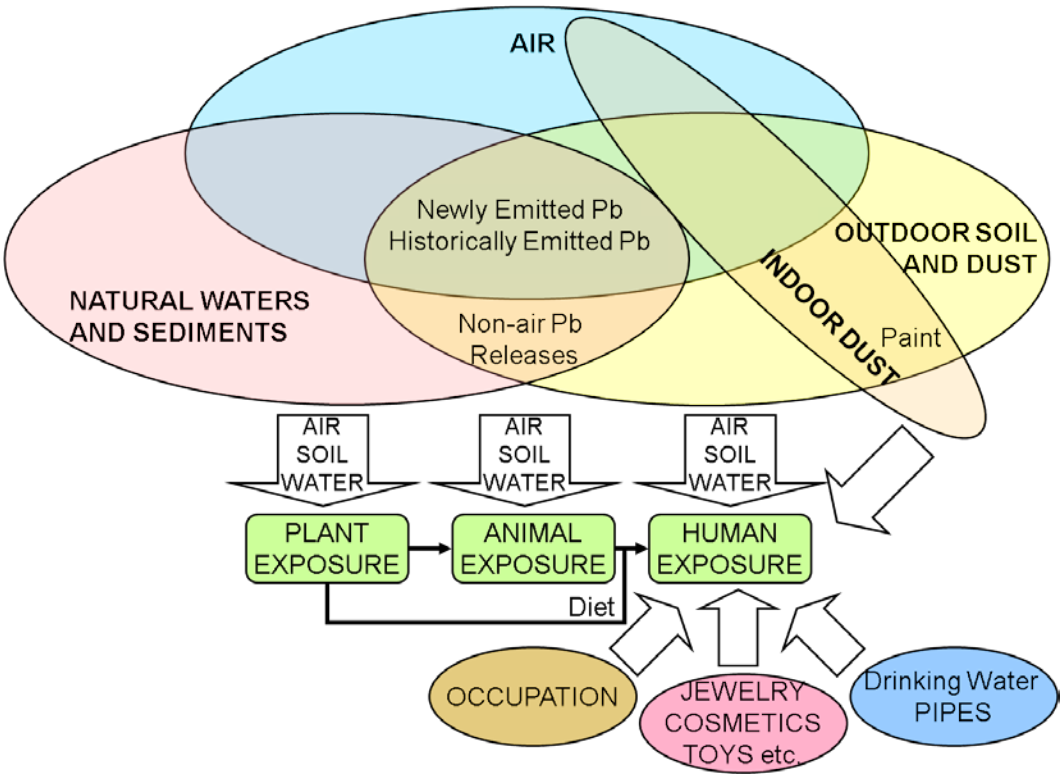
The size distribution of Pb-bearing particulate matter (PM), (i.e., PM having Pb as one of its components) depends on whether there are contributions from industrial sources or

[1] The original indicator for the Pb NAAQS is the mass of the Pb portion of total suspended particles (Pb-TSP). The Pb-TSP indicator was retained in 2008 in recognition of the role of all particulate matter (PM) sizes in ambient air Pb exposures (Section 2.2.2). The Federal Reference Method (FRM) Pb-TSP sampler's size-selective performance is known to be affected by wind speed and direction, and collection efficiency has been demonstrated to decline with particle size. Under certain conditions regulatory Pb monitoring can also be performed for ambient Pb sampled using the FRM for Pb sampled in particles with an upper 50% cut-point of 10 ± 0.5 micrometer (µm) aerodynamic diameter (Pb-PM_{10}). Pb-PM_{10} is allowed in certain instances where the expected Pb concentration does not approach the NAAQS and no sources of ultracoarse Pb particles are nearby.

near-road environments (Section 2.2.2). The size distribution of ambient air Pb-bearing PM is smaller than the size distribution of soil and dust Pb particles containing PM (i.e., soil or dust particles having Pb as one of its components).[1] Coarse Pb-bearing PM (i.e., approximately 2.5 – 10 µm) deposits to a great extent near its source, contributing to local soil Pb contamination, while fine Pb-bearing PM (i.e., smaller than approximately 2.5 µm) can be transported long distances and possibly deposit in remote areas. Depending on local conditions, deposited particles may be resuspended and redeposited multiple times before further transport becomes unlikely.

There are multiple sources of ambient Pb, and human exposure to ambient Pb involves multiple pathways. Figure 1-1 shows how Pb can cycle through multiple environmental media. The "air/soil/water" arrows of the figure depict Pb exposures to plants, animals, and/or humans through contact with Pb-containing media. Air-related pathways of ambient Pb exposure are the focus of this assessment. Air-related ambient Pb exposures include both inhalation of Pb and ingestion of Pb in dust or soil that originated in the ambient air. For example, dietary Pb exposure may be air-related if ambient air Pb deposits on plants or water that become available for human consumption. Dust and soil particles containing Pb are typically in the size range that is ingested rather than inhaled. However, soil can act as a reservoir for deposited Pb emissions, and exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as hand-to-mouth contact, which is the main pathway of childhood exposure to Pb. Non-ambient, non-air-related exposures include hand-to-mouth contact with Pb-containing consumer goods, hand-to-mouth contact with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes.

[1] Pb-bearing PM larger than 10 µm have a sharp concentration gradient with distance from the source, because larger particles have greater settling velocities. Given that wind-related biases strongly affect particles larger than 10 µm, and given that much of the ambient air Pb fraction is smaller than 10 µm, the existing TSP samplers reasonably capture the airborne fraction of ambient Pb that is available for human exposure.



Note: This Venn diagram illustrates the passage of Pb through multiple environmental media compartments through which plant, animal, and human exposures can occur.

Figure 1-1 Conceptual model of multimedia Pb exposure.

The majority of Pb in the body is stored in bone (roughly 90% in adults, 70% in children). Much of the remaining Pb is found in soft tissues; only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to red blood cells [RBCs]). The small fraction of Pb in blood plasma (<1% of Pb in blood) may be the more biologically labile and toxicologically active fraction of the circulating Pb. Both Pb uptake and elimination in soft tissues are much faster than they are in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of exposure. Pb in bone becomes distributed in trabecular (e.g., patella [knee cap]) and the more dense cortical bones (e.g., tibia [shin bone]).

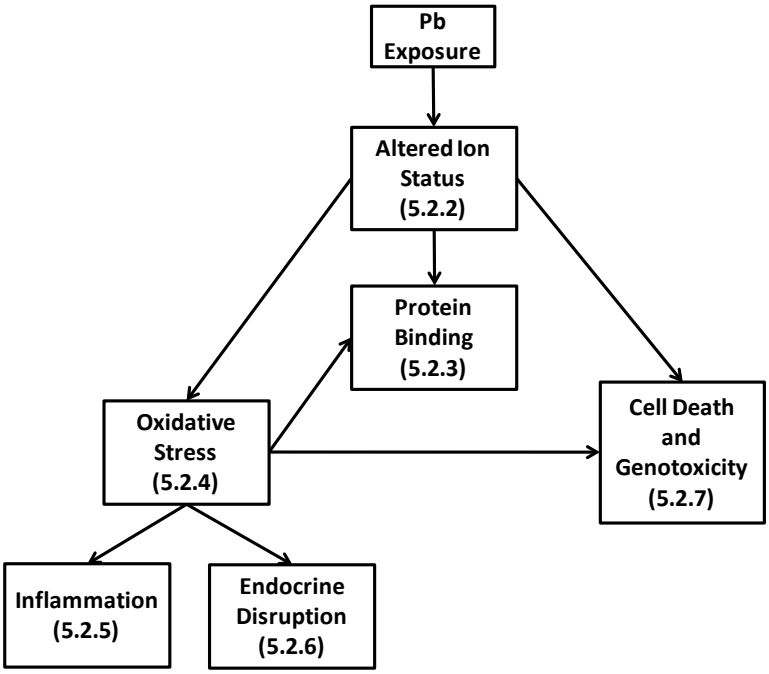
Blood Pb is the most common measure used to estimate Pb dose or exposure in epidemiologic studies of Pb health effects. Overall, blood Pb levels have been decreasing among U.S. children and adults for the past twenty years. The median blood Pb level for the U.S. population is 1.1 micrograms per deciliter (µg/dL), with a 95th percentile blood Pb level of 3.3 µg/dL based on the 2009‑2010 National Health and Nutrition Examination Survey (NHANES) data. Among children aged 1-5 years, the median and 95th percentiles are slightly higher at 1.2 µg/dL and 4.0 µg/dL, respectively. Other

common metrics of Pb dose or exposure used in epidemiologic studies are Pb in bone, which measures cumulative exposure over long periods (months to years), and Pb in cord blood, which is an indicator of prenatal blood Pb concentration.

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines total body burden and the amount of Pb stored in the bone. The contribution of bone Pb to blood Pb changes throughout an individual's life time, and depends on the duration and intensity of the exposure, age, and various other physiological stressors (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) that may affect bone remodeling, which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. Generally, bone Pb is an index of cumulative exposure and body burden. Pb is sequestered in two types of bone compartments; Pb in trabecular bone exchanges more rapidly with the blood than Pb in denser cortical bone. Therefore, Pb in cortical bone is a better marker of cumulative exposure, and Pb in trabecular bone is more likely to be correlated with blood Pb. During pregnancy, Pb is transferred from the mother to the fetus. Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton.

1.3 Integrative Overview of Health and Ecological Effects

There is substantial overlap between the ecological and health endpoints related to Pb exposure, which can be mediated through multiple, interconnected modes of action (MOAs). The cellular/subcellular effect constituting the principal MOA for human health and ecological endpoints is altered ion status. Other related MOAs include protein binding, oxidative stress, inflammation, endocrine disruption, and cell death and genotoxicity (Figure 1-2). Since the mechanisms of Pb toxicity in some organ systems are the same or similar across species, many of the downstream health and ecological effects are similar across species from invertebrates to vertebrates, including humans (Section 2.8.1).



Note: The subsections where these MOAs are discussed are indicated in parentheses.

Figure 1-2 Schematic representation of the relationships between the various MOAs by which Pb exerts its effects.

1.3.1 Health Effects of Pb

Evidence from epidemiologic and toxicological studies was considered in combination with the evidence from other disciplines such as exposure sciences and toxicokinetics in determining the causal relationships for the health endpoints discussed in this assessment. Detailed discussions of the evidence relating to conclusions regarding the health effects of Pb are in Section 2.6 and Chapter 5. The major conclusions regarding health effects from Pb exposure in children and adults are presented in Table 1-1 and summarized below.

Table 1-1 Summary of causal determinations for the relationship between exposure to Pb and health effects.

Health Effect	Causality Determination[a]
Nervous System Effects (Section 2.6.1)	
Cognitive Function Decrements in Children	Causal Relationship
Attention-Related Behavioral Problems in Children	Causal Relationship
Conduct Problems in Children and Young Adults	Likely Causal Relationship
Internalizing Behaviors in Children	Likely Causal Relationship
Sensory Function Decrements in Children	Likely Causal Relationship
Motor Function Decrements in Children	Likely Causal Relationship
Cognitive Function Decrements in Adults	Likely Causal Relationship
Psychopathological Effects in Adults	Likely Causal Relationship
Sensory Function Decrements in Adults	Suggestive of a Causal Relationship
Neurodegenerative Diseases in Adults	Inadequate to Infer a Causal Relationship
Cardiovascular Effects (Section 2.6.2)	
Hypertension	Causal Relationship
Subclinical Atherosclerosis	Suggestive of a Causal Relationship
Coronary Heart Disease	Causal Relationship
Cerebrovascular Disease	Inadequate to Infer a Causal Relationship
Renal Effects (Section 2.6.3)	
Reduced Kidney Function	Likely Causal Relationship
Immune System Effects (Section 2.6.4)	
Atopic and Inflammatory Responses	Likely Causal Relationship
Decreased Host Resistance	Likely Causal Relationship
Autoimmunity	Inadequate to Infer a Causal Relationship
Hematologic Effects (Section 2.6.5)	
Decreased Red Blood Cell Survival and Function	Causal Relationship
Altered Heme Synthesis	Causal Relationship
Reproductive and Developmental Effects (Section 2.6.6)	
Development	Causal Relationship
Birth Outcomes	Suggestive of Causal Relationship
Male Reproductive Function	Causal Relationship
Female Reproductive Function	Suggestive of Causal Relationship
Cancer (Section 2.6.7)	
Cancer	Likely Causal Relationship

[a]Causal determinations were made within approximately 1 order of magnitude of current levels (Preamble, and Section 2.1).

Effects of Pb Exposure in Children

Multiple epidemiologic studies conducted in diverse populations of children consistently demonstrate the harmful effects of Pb exposure on IQ, academic performance, learning and memory. Epidemiologic studies also demonstrate the effect of Pb exposure on inattention, impulsivity, and hyperactivity in children. The evidence in children is supported by findings in animal studies demonstrating both analogous effects and biological plausibility at relevant exposure levels. A decrease in cognitive function has been observed in populations of children 4 to 11 years old with mean blood Pb levels between 2 and 8 μg/dL (Section 2.6.1.1). Evidence suggests that some Pb-related cognitive effects may not be reversible and that neurodevelopmental effects of Pb may persist into adulthood (Section 2.9.4). Pb exposure also causes hematologic effects (such as effects on blood cells or blood producing organs) in children and is associated with an increased risk of internalizing behaviors (e.g., withdrawn behavior and depressive symptoms), sensory and motor function decrements, atopic and inflammatory conditions (e.g., asthma and allergy) in children, as well as misconduct in older children and young adults. Uncertainties arising from the lack of information about the specific Pb-exposure histories which contribute to observed blood Pb levels are greater in adults and older children than in young children (Section 2.9.5). Despite some uncertainties regarding the interpretation of blood Pb levels in older children, it is clear that Pb exposure in childhood presents a risk; further, there is no evidence of a threshold below which there are no harmful effects from Pb exposure.

Effects of Pb Exposure in Adults

A large body of evidence from both epidemiologic studies of adults and experimental studies in animals demonstrates the effect of long-term Pb exposure on increased blood pressure (BP) and hypertension (Section 2.6.2). In addition to its effect on BP, Pb exposure leads to coronary heart disease and death from cardiovascular causes and is likely to cause cognitive function decrements, symptoms of depression and anxiety, reduced kidney function, and immune effects in adult humans. The extent to which the effects of Pb on the cardiovascular system are reversible is not well-characterized. It is also important to note that the frequency, timing, level and duration of Pb exposure causing the effects observed in adults has not been pinpointed, and higher past exposures may well have contributed to the development of health effects measured later in life. However, it is clear that Pb exposure can be harmful to the cardiovascular system and may also affect a broad array of organ systems in adults.

1.3.2 Ecological Effects of Pb

Ecological effects of Pb are summarized for terrestrial, freshwater and saltwater ecosystems, and the ISA discusses endpoints common to plants, invertebrates and vertebrates along with considerations of uncertainties in relating atmospheric Pb concentrations to ecosystem effects. Effects of Pb in ecosystems are primarily associated with Pb deposition onto soil and water, subsequent transport, and exposure through environmental media (soil, water, sediment, biota). The 2006 Pb Air Quality Criteria Document (AQCD) (U.S. EPA, 2006b) and previous EPA assessments reported effects of Pb exposure on both terrestrial and aquatic organisms that included reduced survival, reproduction and growth. Effects on delta-aminolevulinic acid dehydratase (ALAD, an important rate-limiting enzyme needed for heme production), development, and behavior were reported in terrestrial organisms (e.g. birds, mammals), along with decreases in enzyme activity, heme formation, and behavioral effects in aquatic organisms (e.g. fish, aquatic invertebrates). Physiological stress and impacts on hematological and neurobehavioral endpoints may increase susceptibility to other stressors and affect the fitness of individual organisms, and changes in reproduction, growth, and survival are likely to lead to changes in communities and ecosystems. Although increasing exposures generally result in increasing responses in laboratory and field experiments, the relationship of exposure and responses is difficult to characterize quantitatively in natural systems because of the influence of multiple environmental variables on both Pb bioavailability and toxicity, and substantial species and lifestage differences in Pb sensitivity.

A brief discussion of the conclusions from this assessment and earlier Pb AQCDs regarding Pb effects on reproduction, growth, and survival is provided below and summarized in Table 1-2 along with effects of Pb on neurobehavior, hematological, and stress endpoints. Reproduction, growth, and survival are endpoints commonly used in ecological risk assessment because they can lead to effects at the population, community, and ecosystem levels of biological organization. Causal determinations for ecological effects were based on integration of information on biogeochemistry, bioavailability, biological effects, and exposure-response relationships of Pb in terrestrial, freshwater, and saltwater environments. In general, the number of studies available for assessing causality is greater for freshwater organisms than for marine environments. A detailed discussion for all relevant welfare effects (i.e. ecological effects) is provided in Section 2.7 and Chapter 7.

Table 1-2 Summary of causal determinations for the relationship between Pb exposure and effect on plants, invertebrates and vertebrates.

Level		Effect	Terrestrial[a]	Freshwater[a]	Saltwater[a]
Community- and Ecosystem		Community and Ecosystem Effects (Section 2.7.3.7)	Likely Causal	Likely Causal	Inadequate
Population–Level Endpoints	**Organism–Level Responses**	Reproductive and Developmental Effects-Plants (Section 2.7.3.1)	Inadequate	Inadequate	Inadequate
		Reproductive and Developmental Effects-Invertebrates (Section 2.7.3.1)	Causal	Causal	Suggestive
		Reproductive and Developmental Effects- Vertebrates (Section 2.7.3.1)	Causal	Causal	Inadequate
		Growth-Plants (Section 2.7.3.2)	Causal	Likely Causal	Inadequate
		Growth-Invertebrates (Section 2.7.3.2)	Likely Causal	Causal	Inadequate
		Growth-Vertebrates (Section 2.7.3.2)	Inadequate	Inadequate	Inadequate
		Survival-Plants (Section 2.7.3.3)	Inadequate	Inadequate	Inadequate
		Survival- Invertebrates (Section 2.7.3.3)	Causal	Causal	Inadequate
		Survival- Vertebrates (Section 2.7.3.3)	Likely Causal	Causal	Inadequate

		Neurobehavioral Effects- Vertebrates (Section 2.7.3.4)	Likely Causal	Likely Causal	Inadequate
	Sub-organismal Responses	Hematological Effects-Invertebrates (Section 2.7.3.5)	Inadequate	Likely Causal	Suggestive
		Hematological Effects-Vertebrates (Section 2.7.3.5)	Causal	Causal	Inadequate
		Physiological Stress-Plants (Section 2.7.3.6)	Causal	Likely Causal	Inadequate
		Physiological Stress-Invertebrates (Section 2.7.3.6)	Likely Causal	Likely Causal	Suggestive
		Physiological Stress-Vertebrates (Section 2.7.3.6)	Likely Causal	Likely Causal	Inadequate

[a]Based on the weight of evidence for causal determination in Table II of the ISA Preamble. Ecological causal determinations are based on doses or exposures generally within one to two orders of magnitude of the range of Pb currently measured in the environment (Table 2-1).

Effects on Development and Reproduction

Reduced reproduction at the level of individual organisms can result in lowered population numbers and/or extermination, decreased species diversity, and a decline in relative or absolute population numbers at the community level. Effects of Pb on various development, fertility, and hormone maintenance endpoints have been documented in multiple species of terrestrial and freshwater organisms. In plants, only a few studies have addressed reproductive effects of Pb exposure. Among the animal species tested, freshwater invertebrates were the most sensitive to Pb with respect to reproduction (Section 2.7.3.1).

Effects on Growth

Effects on growth observed at the species level can translate into effects at the ecosystem level. Exposure to Pb has been shown to have effects on growth in plants and in some species of invertebrates and vertebrates. Evidence for effects of Pb on growth is strongest in terrestrial plants. These effects are typically found in laboratory studies with high Pb exposure concentrations or in field studies near stationary sources where concentrations are elevated relative to non-polluted locations. Many of those laboratory and field studies evaluate the effects of increasing levels of Pb exposure, and find that effects on plant growth increase with increasing exposure ("biological gradients"). Evidence for Pb effects on growth in invertebrates has been observed most extensively in freshwater aquatic species, with growth inhibition in sensitive species occurring in the range of Pb concentration values available for U.S. surface waters. In general, juvenile organisms are more sensitive than adults. There are only limited data on growth effects in vertebrates (Section 2.7.3.2).

Effects on Survival

Decreased survival of individuals within a population can have ecosystem-level impacts. Pb is generally not toxic to aquatic or terrestrial plants at concentrations found in the environment away from stationary sources, probably due to the fact that plants often sequester large amounts of Pb in roots, with little translocation to other parts of the plant. Aquatic invertebrates are generally more sensitive to Pb exposure than other types of species, with survival reduced in a few species at concentrations occurring near Pb sources, as well as at concentrations occasionally encountered in the general environment (that is, far from major Pb sources). Many terrestrial invertebrates tolerate higher concentrations of Pb. Limited studies with vertebrates showed adverse effects of Pb on survival at concentrations higher than typical ambient Pb levels in the environment, although juvenile organisms are usually more sensitive than adults (Section 2.7.3.3).

Neurobehavioral Effects

Historical and recent evidence from Pb-exposed animals indicates that Pb affects behaviors, such as food consumption, avoidance and escape from predators, behavioral regulation of body temperature, and prey capture. Alterations to these behaviors can decrease the overall fitness of the organism. Evidence from laboratory studies has shown effects of Pb exposure on nervous system endpoints in both terrestrial and freshwater animal taxa (Section 2.7.3.4).

Hematological Effects

Changes in hematological characteristics including ALAD activity, blood cell counts, and serum profiles are associated with Pb exposure in both aquatic and terrestrial animals. It is commonly recognized that ALAD is an indicator of Pb exposure across a wide range of animals as shown in both field and laboratory studies. Studies conducted over the last two decades have shown that hematological responses are associated with Pb in the environment (Section 2.7.3.5).

Effects on Physiological Stress

Increased levels of antioxidant enzymes (in response to oxidative stress or altered cell signaling) and increased lipid peroxidation (the process by which free radicals induce the oxidation of fatty acids, leading to cell membrane damage) are considered to be reliable biomarkers of stress. Alterations in these biomarkers are associated with Pb exposure in plants, invertebrates and vertebrates, and they may be indicative of increased susceptibility to other stressors, as well as reduction in individual fitness. Markers of oxidative damage and antioxidant activity have been observed in field studies in a wide range of species in terrestrial and aquatic environments when Pb is present, and also following laboratory exposures (Section 2.7.3.6).

Community and Ecosystem Effects

The effects of Pb on growth, reproduction, and survival at the level of individual organisms, especially when considered cumulatively, are likely to result in effects on population, community and ecosystem structure and function. Effects at those higher levels of biological organization are confirmed by both laboratory and field experiments in which decreases in abundance, reduced species diversity, and shifts in community composition have been observed following Pb exposure. However, such ecosystem-wide effects can only be tested directly in a few of the cases where individual organism effects are found. Quantitative characterization of exposure-response relationships is difficult at

the community and ecosystem levels because potential confounders such as the presence of other metals, physico-chemical variables and other stressors cannot be controlled and their effects are incompletely characterized (Section 2.7.3.7).

1.4 Policy Relevant Considerations

Public Health Significance

The concept of population risk is relevant to understanding the public health significance of small decrements in IQ and increases in blood pressure caused by Pb exposure. A seemingly small decrease in the population mean IQ or increase in systolic blood pressure may push the most susceptible group in the population to a critical point on the continuum of disease development, such that their condition meets the clinical definition of a disease. For example, increases in blood pressure that are caused by Pb exposure can result in a larger proportion of the population having hypertension. A downward shift in the mean IQ value can result in a larger proportion of the population at risk for academic or vocational failure and can also reduce the proportion of the population achieving very high IQ scores. Moreover, small changes at the population level can translate into large numbers of individual clinical events.

Air Lead(Pb)-to-Blood Lead(Pb) Relationships

A limited number of epidemiological studies evaluated relationships between air Pb and blood Pb (Section 2.9.2). Regression models are typically used to produce slopes that estimate the change in blood Pb per change in air Pb concentration (µg/dL per µg Pb/m^3). The larger the slope, the larger the estimated contribution of air Pb is to the blood Pb level in exposed populations.

The range of air-to-blood slope estimates is 2 to 9 µg/dL per µg/m^3 in studies of children. The differences in the estimates across studies, at least in part, reflect the choice of model (e.g., some models predict an increase in the blood Pb-air Pb slope with decreasing air Pb concentration while other models predict a constant blood Pb-air Pb slope across all air Pb concentrations) as well as the terms that are included in the model (e.g., soil Pb) that may account for some of the variation in blood Pb that is attributable to air Pb. Other factors that may explain the variation in the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources (e.g., leaded gasoline or smelter).

Concentration-Response Relationships for Health Effects

Previous assessments found that progressively lower blood Pb levels were associated with cognitive deficits in children and newly available evidence is generally consistent with findings of the previous review (Section 2.9.3). Compelling evidence for a larger effect of Pb on children's IQ at lower blood Pb levels compared to higher blood Pb levels was presented in the 2006 Pb AQCD based on the international pooled analysis of seven prospective cohort studies. A subsequent reanalysis of these data focusing on the shape of the concentration-response function and several recent studies support the findings of the original the pooled analysis. The majority of the epidemiologic evidence from stratified analyses comparing the lower and the higher ends of the blood Pb distributions also indicates larger effect of Pb on IQ at lower blood Pb levels. The shape of concentration-response relationships is not well characterized for effects of Pb in adults (Section 2.9.3).

Patterns of Pb Exposure and Neurodevelopmental Deficits in Children

Among the populations included in epidemiologic studies using blood Pb as a metric of Pb exposure, the relative proportion of blood Pb derived from recent versus past exposure cannot be fully characterized in the absence of detailed information on exposure history. Uncertainty regarding the role of recent exposure is greater in adults and older children than in young children who do not have lengthy exposure histories. Several lines of evidence inform the interpretation of epidemiologic studies of young children with regard to the patterns of exposure that contribute to observed health effects (Section 2.9.4). In summary, epidemiologic studies find associations of cognitive function and/or attention related behavior problems with several different blood Pb exposure metrics that represent blood Pb during lifestages from prenatal to adolescence. These findings are generally consistent with Pb effects reported in experimental animal studies and are consistent with the fact that the nervous system continues to develop throughout childhood.

Potentially At-Risk Populations

The NAAQS are intended to protect public health with an adequate margin of safety. In so doing, protection provided for both the population as a whole and those groups at increased risk for health effects in response to the air pollutant for which each NAAQS is set. Children are at increased risk for the effects of Pb exposure. Among children, the youngest age groups were observed to be most at risk of elevated blood Pb levels, with levels decreasing with increasing age of the children. Evidence related to childhood and other at-risk factors is described in Section 2.9.6.

Pb Concentrations Corresponding to Ecological Effects

There is limited evidence to relate ambient air concentrations of Pb to levels of deposition onto terrestrial and aquatic ecosystems and to subsequent movement of atmospherically-deposited Pb through environmental compartments (e.g., soil, sediment, water, and biota) (Section 2.9.7). The contribution of atmospheric Pb to specific sites is not clear and the connection between air concentration of Pb and ecosystem exposure continues to be poorly characterized. Furthermore, the level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems, due to the influence of other environmental variables (e.g., pH, organic matter) on both Pb bioavailability and toxicity, and also to substantial species differences in Pb sensitivity. Current evidence indicates that Pb is bioaccumulated in biota; however, the sources of Pb in biota have only been identified in a few studies, and the relative contribution of Pb from all sources is usually not known.

1.5 Summary

Overall, the evidence evaluated for the current review expands upon findings of the 2006 Pb AQCD and previous assessments, which concluded that there was a strong body of evidence substantiating the health effects from Pb exposure as well as strong evidence of the effects from Pb exposure on some ecological endpoints.

Nervous system effects in children, specifically cognition problems in children, are the effects that are best substantiated as occurring at the lowest blood Pb concentrations (Section 2.6.1.1). Causal relationships were also determined for several cardiovascular effects in adults, for which the evidence strongly suggests that long-term Pb exposure plays a role. Since Pb exposures were generally higher in the past than they are today, uncertainties still exist regarding the relative importance of recent versus past exposure in the development of the Pb-related health effects in the adult populations studied.

With regard to the ecological effects of Pb, uptake of Pb into fauna and subsequent effects on reproduction, growth and survival are established and are further supported by more recent evidence. These may lead to effects at the population, community, and ecosystem level of biological organization. In both terrestrial and aquatic organisms, gradients in response are observed with increasing concentration of Pb and some studies report effects within the range of Pb detected in environmental media. Specifically, observations from controlled studies on reproduction, growth, and survival in sensitive freshwater invertebrates are well-characterized at concentrations at or near Pb concentrations occasionally encountered in U.S. surface waters. Hematological and stress

related responses were also associated with elevated Pb levels in polluted areas in some terrestrial and aquatic species. However, in natural environments, modifying factors affect Pb bioavailability and toxicity and there are considerable uncertainties associated with generalizing effects observed in controlled studies to effects at higher levels of biological organization. Furthermore, available studies on community and ecosystem-level effects are usually from contaminated areas where Pb concentrations are much higher than typically encountered in the environment. The contribution of atmospheric Pb to specific sites is not clear and the connection between air concentration of Pb and ecosystem exposure continues to be poorly characterized. Furthermore, the level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems, due to the influence of other environmental variables (e.g., pH, organic matter) on both Pb bioavailability and toxicity, and also to substantial species differences in Pb sensitivity.

2 INTEGRATIVE SUMMARY

2.1 ISA Development and Scope

This chapter summarizes and synthesizes the recently available scientific evidence and is intended to provide a concise synopsis of the ISA conclusions and findings that best inform the review of the current NAAQS for lead (Pb). *The Integrated Review Plan (IRP) for the National Ambient Air Quality Standards for Lead* (U.S. EPA, 2011c) identifies a series of policy-relevant questions (in Chapter 3) that provide the framework for this assessment, and which also frames the entire review of the NAAQS for Pb, and thus are informed by both science and policy considerations. The plans and underlying questions for the ISA are included in the IRP. The ISA organizes, presents, and integrates the scientific evidence, which is considered along with findings from any risk analyses and policy considerations, to help the U.S. Environmental Protection Agency (EPA) address these questions during the NAAQS review for Pb. The ISA includes:

- An integration of the evidence on the human health effects associated with Pb exposure, discussion of important uncertainties identified in the interpretation of the scientific evidence, and an integration across different scientific disciplines and across individual endpoints within major outcome categories.
- An integration of the evidence on the welfare effects of Pb in terrestrial, freshwater and saltwater ecosystems, discussion of endpoints common to plants, invertebrates and vertebrates and consideration of uncertainties in relating atmospheric Pb concentrations to welfare effects.
- An integration of the effects associated with exposure to Pb across the scientific disciplines for health and ecology, focusing on common modes of action.
- Discussion of policy relevant considerations, such as potentially at-risk populations and concentration-response relationships.

EPA has a systematic process for evaluating the scientific evidence and for drawing conclusions and judgments regarding the causal association of air pollution with health and environmental effects. The ISA process includes literature search strategies, criteria for selecting and evaluating studies, approaches for evaluating weight of the evidence, and a framework for making causality determinations. As part of this process, the ISA is reviewed by the public and peer reviewed by a formal panel of scientific experts (the Clean Air Scientific Adviory Committee [CASAC]). The process and causality

framework are described in more detail in the Preamble to the ISA. This section provides a brief overview of the process for development of this ISA.

EPA initiated the current review of the NAAQS in February 2010 with a call for information from the public (75 FR 8934). Literature searches were conducted routinely to identify studies published since the last review, focusing on studies published from 2006 (close of previous scientific assessment) through September 2011. References that were considered for inclusion or cited in this ISA can be found at http://hero.epa.gov/lead.

This ISA evaluates relevant epidemiologic, animal toxicological, and welfare effects studies, including those related to concentration-response relationships, mode(s) of action (MOA), and susceptible populations. Additionally, air quality and emissions data, studies on environmental fate and transport, and issues related to Pb toxicokinetics and exposure were considered for inclusion in the document. Previous AQCDs (U.S. EPA, 2006b, 1986b, 1977) have included an extensive body of evidence on these topics. In this ISA, the conclusions and key findings from previous reviews are summarized at the beginning of each section, to provide the foundation for consideration of evidence from recent studies. Results of key studies from previous reviews are included in discussions or tables and figures, as appropriate, and conclusions are drawn based on the synthesis of evidence from recent studies with the extensive literature summarized in previous reviews.

The Preamble discusses the general framework for conducting the science assessment and developing an ISA, including criteria for selecting studies for inclusion in the ISA evaluating and integrating the scientific evidence and developing scientific conclusions. In selecting the studies for inclusion in the Pb ISA, particular emphasis is placed on those studies most relevant to the review of the NAAQS.

In drawing judgments regarding causality for the criteria air pollutants, evidence of health effects in the range of relevant pollutant exposures or doses is considered. With regard to the causal determinations drawn for human health effects of Pb, population-based epidemiology studies were emphasized over occupational studies. Recent occupational studies were considered insofar as they addressed a topic area that was of particular relevance to the NAAQS review (e.g., longitudinal studies designed to examine recent versus historical Pb exposure). Evidence from toxicological studies of effects observed in experimental animals at doses that were relevant to, or somewhat above, those currently experienced by the U.S. general population were emphasized. Generally studies with blood Pb levels within one order of magnitude above the upper end of the distribution of

U.S. blood Pb levels were considered in forming conclusions[1] with the majority of studies reporting blood Pb levels below 25-30 µg/dL. Studies with higher blood Pb levels were considered if they informed the evaluation of modes of action, mechanisms, or kinetics. For toxicological studies where blood Pb levels were not measured, judgments regarding how to distinguish high from the more relevant low doses were made considering the range of doses across the available body of evidence and emphasizing studies at the lower end of the range.

Relevant concentrations for drawing causality judgments for the welfare effects of Pb were determined considering the range of Pb concentrations in the environment and the available evidence for concentrations at which effects were observed in plants, invertebrates, and vertebrates. Effects observed at or near ambient Pb concentrations measured in soil, sediment and water in the most recent available studies (Table 2-1) were emphasized and studies generally within one to two orders of magnitude above the reported range of these values were considered in the body of evidence for terrestrial, freshwater and saltwater ecosystems. Studies at higher concentrations were used to the extent that they informed modes of action and illustrated the wide range of sensitivity to Pb across taxa.

The causal determinations for terrestrial, freshwater and saltwater effects are divided into two categories. The first category includes endpoints that are commonly used in ecological risk assessment (reproduction, growth, and survival). It is clear that these endpoints can lead to population-level (e.g., abundance, production, extirpation), community-level (e.g., taxa richness, relative abundance) and ecosystem-level effects (Ankley et al., 2010; Suter et al., 2005). The second category includes organism- and sub-organism-level responses such as physiological stress, hematological effects, and neurobehavioral effects. As recognized in EPA's Framework for Ecological Risk Assessment (U.S. EPA, 1992), and in the adverse outcome pathway (AOP) framework (Ankley et al., 2010) endpoints that are measured at one level of biological organization may be related to an endpoint at a higher level. The AOP conceptual framework was proposed to link mechanistic data from initiating events at the molecular level through a series of higher order biological responses to growth, survival and reproductive endpoints that can be used in ecological risk assessment, i.e., at the population level and higher. In the case of Pb, sub-organismal responses (i.e., physiological stress, hematological effects) and organism-level responses (neurobehavioral alterations) may decrease the overall fitness of an organism, even though their connection to effects at higher levels of biological organization may not have been characterized. Furthermore, the effects of Pb

[1] For example, the 97.5th percentile of the NHANES distribution of blood Pb level in children 1-5 years old is 5 µg/dL; however, the proportion of individuals with blood Pb levels that exceed this concentration varies depending on factors including age and sex (Section 4.1).

on ecosystems necessarily begin with some initial effects at the molecular level of specific organisms within the ecosystem (U.S. EPA, 1986b). There are many different molecular and cellular level effects, and toxicity of Pb in ecosystems may be attained through multiple modes of action.

The ISA considers evidence of health effects for both short- and long-term pollutant exposures. Since biomarkers are typically used as an index of exposure or dose in epidemiologic studies, there is uncertainty regarding the timing, frequency, level, and duration of the exposure(s) associated with the blood Pb (or other biomarker) levels measured in these studies. Some animal toxicological studies provide evidence to inform the exposure patterns that are needed to induce effects in animals and these studies are drawn upon to interpret the human health effects evidence. Exposure regimens used in toxicological studies typically include chronic exposure (i.e., over 10% of the lifespan of the animal), long-term exposure (e.g., greater than 4 weeks in rodents) and acute or short-term exposure (e.g., less than 4 weeks in rodents). For the purpose of this assessment, short-term human exposures are generally defined to include exposures of months (e.g., <one year) while long-term human exposures include those greater than one year in duration. Information including the age of the population studied, study period and study location is also used to aid in the interpretation of findings from epidemiologic studies because Pb exposures have declined over time and exposures vary depending on proximity to Pb sources.

This ISA uses a five-level hierarchy that classifies the weight of evidence for causation:

- Causal relationship
- Likely to be a causal relationship
- Suggestive of a causal relationship
- Inadequate to infer a causal relationship
- Not likely to be a causal relationship

Beyond judgments regarding causality are questions relevant to quantifying health or environmental risks based on the understanding of the quantitative relationships between pollutant exposures and health or welfare effects. Once a determination is made regarding the causal relationship between the pollutant and outcome category, important questions regarding quantitative relationships include:

- What is the concentration-response, exposure-response, or dose-response relationship in the human population?

- What exposure conditions (dose or exposure, exposure pathways, duration and pattern) are important?
- What populations and lifestages appear to be differentially affected i.e., at greater risk of Pb-related health effects?
- What elements of the ecosystem (e.g., types, regions, taxonomic groups, populations, functions, etc.) appear to be affected or are more sensitive to effects?

This ISA is composed of seven chapters including the Executive (Chapter 1) and Integrative Summaries (Chapter 2). Chapter 3 highlights key concepts or issues relevant to understanding the sources, ambient concentrations, and fate and transport of Pb in the environment. Chapter 4 summarizes key concepts and recent findings on Pb exposures, toxicokinetics, and biomarkers reflecting Pb exposure and body burden. Chapter 5 presents a discussion of the MOA of Pb and evaluates and integrates epidemiologic and animal toxicological information on health effects related to Pb exposure. Chapter 6 summarizes the evidence on potentially susceptible populations. Chapter 7 evaluates welfare effects evidence that is relevant to the review of the secondary NAAQS for Pb.

This chapter summarizes and integrates the newly available scientific evidence that best informs consideration of the policy-relevant questions that frame this assessment. The organization of this chapter generally follows the organization of the document as a whole, with several additional sections including: a discussion of the assessment development and scope (Section 2.1); an integration of the evidence across the disciplines of health and ecology (Section 2.8); a discussion of policy-relevant considerations (Section 2.9); and, an overall summary (Section 2.10).

2.2 Ambient Pb: Source to Concentration

2.2.1 Sources, Fate and Transport of Ambient Pb

The findings of this review build upon those from the 2006 Pb AQCD (U.S. EPA, 2006b), which documented the decline in ambient air Pb emissions following the phase out on alkyl-Pb additives for on-road gasoline and reductions in industrial facility emissions of Pb. Pb emissions declined by 98% from 1970 to 1995 and then by an additional 76% from 1995 to 2008. The 2008 National Emissions Inventory (NEI) reported ambient air Pb emissions of 964 tons. Air Pb emissions represent just a small fraction (by weight) of the Pb used in U.S. production.

According to the 2008 NEI (U.S. EPA, 2011a), piston-engine aircraft emissions comprise the largest share (57%) of total atmospheric Pb emissions. Other sources of ambient air Pb, beginning with the largest, include metal working and mining, fossil fuel combustion, other industrial sources, and roadway related sources. Although piston-engine aircraft collectively comprise the largest emissions source, the highest emitting individual industrial sites produce more ambient air Pb emissions than individual airports.

Global atmospheric Pb deposition peaked in the 1970s, followed by a decline (Section 3.2). Pb deposition is greater near Pb emission sources. Both wet and dry deposition are important mechanisms for removing Pb from the atmosphere, and the atmosphere is the main environmental transport pathway for Pb which is deposited onto surface water and soil. Wet deposition is more important for the fine fraction while the coarse fraction is usually removed by dry deposition. Pb associated with coarse PM deposits to a great extent near local industrial sources, contributing to soil Pb concentrations in those locations, while fine Pb-bearing PM can be transported long distances, contributing Pb contamination in remote areas. Depending on local conditions, once deposited particles may be resuspended and redeposited before reaching a site where further transport is unlikely, especially for dry deposition (Section 3.3). Surface waters act as an important reservoir, with Pb lifetimes in the water column largely controlled by deposition and resuspension of Pb in sediments. Substantial amounts of Pb from vehicle wear and building materials can also be transported by runoff waters to surface waters and sediments without becoming airborne. Pb containing sediment particles can be remobilized into the water column, and sediment concentrations tend to follow those in overlying waters (Section 3.3).

2.2.2 Monitoring and Concentrations of Ambient Air Pb

The indicator for the Pb NAAQS is Pb in total suspended particles (Pb-TSP). The Federal Reference Method (FRM) for Pb-TSP specifies that ambient air is drawn through a high-volume TSP sampler onto a glass fiber filter. The Pb-TSP sampler's size selective performance is known to be affected by wind speed and direction, and collection efficiency has been demonstrated to decline with increasing particle size with an uncertain upper size limit (Wedding et al., 1977). There have been only a few studies since the publication of the 2006 Pb AQCD with regard to sampling error in the Pb-TSP FRM or alternatives to the existing Pb-TSP sampling technology. In addition to monitors used historically for sampling Pb-PM, several single stage and multi-stage impactors and inlets used for sampling PM concentrations are also potential options for Pb-PM monitoring when the majority of particles are smaller than 15 μm. Given that most sites with collocated Pb-PM_{10} and Pb-TSP monitors have average Pb-PM_{10}:Pb-TSP ratios

greater than 0.75 (Section 3.5.3), the existing samplers reasonably capture the airborne fraction of ambient Pb that is available for human exposure (Section 3.4.1).

Ambient air Pb monitoring requirements have undergone several changes since publication of the 2006 Pb AQCD. The current Pb monitoring network design requirements include two types of FRM monitoring sites: source-oriented and non-source-oriented (Section 3.4). For the purpose of analyzing data for the ISA, monitors reporting to the U.S. EPA Air Quality System (AQS) database were considered to be source-oriented if they were designated in AQS as source-oriented, or if they were located within 1 mile of a 0.5 ton per year or greater source, as noted in the 2005 NEI (U.S. EPA, 2008a) or the 2008 NEI (U.S. EPA, 2011a). Source-oriented FRM Pb-TSP monitoring sites are required near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. Non-source-oriented FRM (Pb-TSP or Pb-PM_{10}) monitoring is also required at national core multipollutant monitoring network (NCore) sites in Core Based Statistical Areas (CBSA) with a population of at least 500,000. In addition to FRM monitoring, Pb is also routinely measured in smaller particle fractions in the chemical speciation network (CSN), interagency monitoring of protected visual environment (IMPROVE), and the national air toxics trends station (NATTS) networks. While monitoring in multiple networks provides extensive geographic coverage, measurements between networks are not directly comparable in all cases because there are differences in the methods, including the different particle size ranges sampled in the different networks. Depending on monitoring network, Pb is monitored in TSP, PM_{10}, or $PM_{2.5}$.

Ambient air Pb concentrations have declined drastically over the period 1980-2010 (Section 3.5). The median annual concentrations have dropped by 97% from 0.87 $\mu g/m^3$ in 1980 to 0.03 $\mu g/m^3$ in 2010. The mean source-oriented Pb maximum 3-month average concentration was skewed toward the 75th percentile of the data distribution and exceeded the level of the NAAQS, suggesting that ambient air Pb concentrations are high near a subset of industrial sources of airborne Pb. Studies in the peer-reviewed literature have shown slightly elevated Pb concentrations downwind of industrial sources and airports. Estimates for the natural background Pb concentrations from sources including volcanoes, sea-salt spray, and biogenic sources are ~0.00002 to 0.001 $\mu g/m^3$. These estimates indicate that background airborne Pb concentrations are well below current ambient concentrations.

The size distribution of Pb-bearing PM has changed over time and varies by site (Section 3.5.3). Recent study results indicate that the size distribution has shifted upward since the 1980s, with the mode of the size distribution of Pb-PM particles now falling between 2.5 μm and 10 μm (Cho et al., 2011). The Pb-PM size distribution depends on

whether there are contributions from industrial sources or near-road environments. In contrast to Cho et al. (2011), analysis of the distributional properties of the Pb-PM measured by the AQS monitors, which are often sited near sources, suggests that the largest proportion of particles is still below 2.5 μm in diameter.

2.2.3 Ambient Pb Concentrations in Non-Air Media and Biota

Releases of Pb to the atmosphere have led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with highest concentrations near Pb sources, such as smelters. After the phase-out of Pb from on-road gasoline, Pb concentrations have decreased considerably in rain, snowpack, and surface waters.

Declining Pb concentrations in tree foliage, trunk sections, and grasses, as well as surface sediments and soils, have also been observed (U.S. EPA, 2006b).

Often, Pb is retained in soils and sediments, where it provides a historical record of deposition. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth and indicate peak concentrations between 1960 and 1980 (when leaded on-road gasoline was at peak use). Concentrations of Pb in moss, lichens, peat, and aquatic bivalves have been used to understand spatial and temporal distribution patterns of air Pb concentrations. Ingestion and water intake are the major routes of Pb exposure for aquatic organisms, and food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife.

Overall, Pb concentrations have decreased substantially in media through which Pb is rapidly transported, such as air and water. Substantial Pb remains in soil and sediment sinks. In areas less affected by major local sources, the highest concentrations are below the surface layers and reflect the phase-out of Pb from on-road gasoline and emission reductions from other sources.

Information on ambient Pb concentrations in non-air media and biota is reported in Section 3.6, and concentrations considered in the interpretation of the ecological evidence are tabulated in Table 2-1. As noted in the preamble, the ecological causal determinations focus on studies where effects of Pb exposure are observed at or near ambient levels of Pb and studies generally within the range of one to two orders of magnitude above current or ambient conditions were also considered in the body of evidence.

Table 2-1 Ambient Pb concentrations in non-air media and biota considered for ecological assessment.

Media	Pb Concentration	Years Data Obtained	References
Soil	National Average: 18.9 mg Pb/kg (dry weight) Range of state averages: 5-38.6 mg Pb/Kg (dry weight)	1961-1997	U.S. EPA (2007d, 2006b, 2003b)
Freshwater Sediment	Median: 73 mg Pb/kg (dry weight)	1996-2001	Mahler et al. (2006)
	Median: 28 mg Pb/kg[b] (dry weight)	1991-2003	U.S. EPA (2006b)
Saltwater Sediment	Range: 0.6 to 1,050 mg Pb/kg[a]	Dates not available	Sadiq (1992)
Fresh Surface Water (Dissolved Pb)[b]	Median: 0.50 µg Pb/L[b]; Max: 30 µg Pb/L, 95th percentile 1.1 µg Pb/L	1991-2003	U.S. EPA (2006b)
	Range: 0.0003-0.075 µg Pb/L (Set of National Parks in western U.S.)	2002-2007	Field and Sherrell (2003), U.S. National Park Service (2011)
Saltwater[c]	Range: 0.01–27 µg Pb/L	Dates not available	Sadiq (1992)
Vegetation	Lichens: 0.3-5 mg Pb/kg (dry weight) (Set of National Parks in western U.S.)	2002-2007	U.S. National Park Service (2011)
	Grasses: 31% (percent of soil Pb in grass)	1980s-2000s	Vandenhove et al. (2009)
Vertebrates	Fish: Geometric Mean: 0.59 mg Pb/kg (dry weight) (whole fish) 0.15 mg Pb/kg (dry weight) (liver) Range: 0.08-22.6 mg Pb/kg (dry weight) (whole fish) 0.01-12.7 mg Pb/kg (dry weight) (liver)	1991-2001	U.S. EPA (2006b)
	Fish (from a set of national parks in western U.S.): 0.0033 (fillet) to 0.97 (liver) mg Pb/kg (dry weight) Moose[d]: 0.008-0.029 mg Pb/kg (dry weight) (meat) 0.012-0.023 mg Pb/kg (dry weight) (liver)	2002-2007	U.S. National Park Service (2011)

[a]No information available regarding wet or dry weight

[b]Based on synthesis of National Water-Quality Assessement (NAWQA) data reported in 2006 Pb AQCD (U.S. EPA, 2006b)

[c]Data from a combination of brackish and marine saltwater samples. In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems.

2.3 Exposure to Ambient Pb

Human Pb exposure is difficult to assess because Pb has multiple sources in the environment and passes through various media (Section 4.1). Air-related pathways of Pb exposure are the focus of this assessment. In addition to inhalation of Pb in ambient air, air-related Pb exposure pathways include inhalation and ingestion of Pb in indoor dust and/or outdoor soil that originated from recent or historic ambient air (e.g., air Pb that has penetrated into the residence either via the air or tracking of soil), ingestion of Pb in drinking water drawn from surface water contaminated from atmospheric deposition or contaminated from surface runoff of deposited Pb, and ingestion of Pb in dietary sources after uptake by plants or grazing animals. Soil can act as a reservoir for deposited Pb emissions. Exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as shoe tracking and hand-to-mouth contact, which is the main pathway of childhood air-related exposure to Pb. Non-ambient air-related exposures include hand-to-mouth contact with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes. Several study results indicate that Pb-containing paint in the home and home age (often a surrogate for the presence of Pb paint) are important residential factors that increase risk of elevated blood Pb (Sections 2.9.6 and 6.2.6). Most Pb biomarker studies do not indicate species or isotopic signature. As a consequence, non-air exposures are reviewed in this section, because they can also contribute to Pb body burden.

A number of monitoring and modeling techniques have been employed for ambient Pb exposure assessment. Environmental Pb concentration data can be collected from ambient air Pb monitors, soil Pb samples, dust Pb samples, and dietary Pb samples to estimate human exposure. Exposure estimation error depends in part on the collection efficiency of these methods; collection efficiency for ambient air Pb FRM samplers is described in Section 3.4. Additionally, high spatial variability of the Pb concentrations in various media also can contribute to exposure error, as described in the 2009 PM ISA (U.S. EPA, 2009a). Models, such as the Integrated Exposure Uptake Biokinetic (IEUBK) model, simulate human exposure to Pb from multiple sources and through various routes including inhalation and ingestion. IEUBK model inputs include soil-Pb concentration, air-Pb concentration, dietary-Pb intake including drinking water, Pb-dust ingestion, human activity, and biokinetic factors. Measurements and/or assumptions can be utilized when formulating the model inputs; errors in measurements and assumptions thus have the potential to propagate through exposure models.

The size distribution of dust particles containing Pb differs from the size distribution of inhalable ambient Pb-bearing PM (Sections 3.5 and 4.1). Airborne particles containing Pb tend to be small (much of the distribution <10 µm) compared with soil or dust particles containing Pb (~50 µm to several hundred µm). Ingestion through hand-to-mouth contact is the predominant exposure pathway for the larger particles in soil and dust containing Pb.

2.4 Toxicokinetics

The majority of Pb in the body is found in bone (roughly 90% in adults, 70% in children); only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to red blood cells (RBCs). It has been suggested that the small fraction of Pb in plasma (<1%) may be the more biologically labile and toxicologically active fraction of the circulating Pb. The relationship between Pb in blood and plasma is pseudo-linear at relatively low daily Pb intakes (i.e., <10 µg/day–kg) and at blood Pb concentrations <25 µg/dL, and becomes curvilinear at higher blood Pb concentrations due to saturable binding to RBC proteins. As blood Pb level increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues. See Section 4.2 for additional details.

The burden of Pb in the body may be viewed as divided between a dominant slow (i.e., uptake and elimination) compartment (bone) and smaller fast compartment(s) (soft tissues). Pb uptake and elimination in soft tissues is much faster than in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of exposure. During infancy and childhood, bone calcification is most active in trabecular bone (e.g., patella); whereas, in adulthood, calcification occurs at sites of remodeling in cortical (e.g., tibia) and trabecular bone (Aufderheide and Wittmers, 1992). A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, in early childhood bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, much of the Pb acquired early in life is not permanently fixed in the bone.

The exchange of Pb from plasma to the bone surface is a relatively rapid process. Pb in bone becomes distributed in trabecular and the more dense cortical bone. The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80% cortical to 20% trabecular. Of the bone types, trabecular bone is more reflective of recent exposures than is cortical bone due to the slow turnover rate and lower blood perfusion of cortical bone. Some Pb diffuses to deeper bone regions where it is relatively inert, particularly in adults. These bone compartments are much more labile in infants

and children than in adults as reflected by half-times for movement of Pb from bone into the plasma (e.g., cortical half-time = 0.23 years at birth, 3.7 years at 15 years of age, and 23 years in adults; trabecular half-time = 0.23 years at birth, 2.0 years at 15 years of age, and 3.8 years in adults) (Leggett, 1993). See Section 4.2 for additional details.

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood to maternal blood Pb ratios (i.e., cord blood Pb concentration divided by mother's blood Pb). Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL. Some evidence suggests the ratio of cord blood Pb to maternal blood Pb may decrease with decreasing maternal blood Pb (Section 4.2.2.4). Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton. See Section 4.2 for additional details.

The dominant elimination phase of Pb kinetics in the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days. An abrupt change in Pb uptake gives rise to a relatively rapid change in blood Pb, to a new quasi-steady state, achieved in ~75-100 days (i.e., 3-4 times the blood elimination half-life). A slower phase of Pb clearance from the blood may become evident with longer observation periods following a decrease in exposure due to the gradual redistribution of Pb among bone and other compartments. See Section 4.3 for additional details.

2.5 Pb Biomarkers

Overall, trends in blood Pb levels have been decreasing among U.S. children and adults over the past 20 years (Section 4.4). The median blood Pb level for the entire U.S. population is 1.1 µg/dL and the 95th percentile blood Pb level is 3.3 µg/dL, based on the 2009-2010 National Health and Nutrition Examination Survey (NHANES) data (NCHS, 2010). Among children aged 1-5 years, the median and 95th percentiles were slightly higher, at 1.2 µg/dL and 4.0 µg/dL, respectively.

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines body burden and Pb in bone. The contribution of bone Pb to blood Pb changes, depending on the duration and intensity of the exposure, age, and various other physiological stressors (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) that may affect bone remodeling, which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. In adults and children, where exposure to Pb has

effectively ceased or greatly decreased, there is a rapid decline in blood Pb over the first few months followed by a more gradual, slow decline in blood Pb concentrations over the period of years due to the gradual release of Pb from bone. Bone Pb is an index of cumulative exposure and body burden. Even bone compartments should be recognized as reflective of differing exposure periods with Pb in trabecular bone exchanging more rapidly than Pb in cortical bone with the blood. Consequently, Pb in cortical bone is a better marker of cumulative exposure, while Pb in trabecular bone is more likely to be correlated with blood Pb, even in adults. See Section 4.3 for additional details.

Sampling frequency is an important consideration when evaluating blood Pb and bone Pb levels in epidemiologic studies, particularly when the exposure is not well characterized. It is difficult to determine what blood Pb is reflecting in cross-sectional studies that sample blood Pb once, whether recent exposure or movement of Pb from bone into blood from historical exposures. In contrast, cross-sectional studies of bone Pb and longitudinal samples of blood Pb concentrations over time provide more of an index of cumulative exposure and are more reflective of average Pb body burdens over time. The degree to which repeated sampling will reflect the actual long-term time-weighted average blood Pb concentration depends on the sampling frequency in relation to variability in exposure. High variability in Pb exposures can produce episodic (or periodic) oscillations in blood Pb concentration that may not be captured with low sampling frequencies. Furthermore, similar blood Pb concentrations in two individuals (or populations), regardless of their age, do not necessarily translate to similar body burdens or similar exposure histories.

The concentration of Pb in urine follows blood Pb concentration. There is added complexity with Pb in urine because concentration is also dependent upon urine flow rate, which requires timed urine samples that is often not feasible in epidemiologic studies. Other biomarkers have been utilized to a lesser extent (e.g., Pb in teeth). See Section 4.3.

2.6 Health Effects

This section summarizes and evaluates the evidence from toxicological and epidemiologic studies of the health effects associated with Pb exposure and integrates that evidence across these disciplines. The coherence of evidence across toxicological and epidemiologic findings and across a spectrum of related endpoints, including evidence for mode of action (MOA), is evaluated to establish biological plausibility and address uncertainties in the epidemiologic evidence due to biases from factors such as selective publication of positive results, recruitment or participation of subjects; reverse

causality; or confounding. Information on the frequency, timing, level and duration of exposure in animal toxicological studies is used to inform the interpretation of epidemiologic studies regarding the relevant patterns of exposure that are likely associated with the health effects. The results from the health studies are also considered in combination with the evidence from other fields (e.g., toxicokinetics, exposure science) to draw conclusions regarding the causal relationship between Pb exposure and the health effects evaluated in this assessment (Table 2-2). A more detailed discussion of the underlying evidence used to formulate each causal determination can be found in Chapter 5 of this document.

Table 2-2 Summary of causal determinations between exposure to Pb and health outcomes.

Health Outcome	Causality Determination[a] (Table with Key Supporting Evidence)
Nervous System Effects (Section 5.3.16)	
Children	
Cognitive Function Decrements (e.g., Full Scale IQ [FSIQ], learning)	Causal Relationship (Table 5-17)
Attention-Related Behavioral Problems (e.g., inattention, impulsivity, hyperactivity)	Causal Relationship (Table 5-17)
Conduct Problems in Children and Young Adults (e.g., parent/teacher conduct ratings, criminal offenses)	Likely Causal Relationship (Table 5-17)
Internalizing Behaviors (e.g., withdrawn behavior, symptoms of depression)	Likely Causal Relationship (Table 5-17)
Sensory Function Decrements (e.g., hearing threshold, electroretinography [ERG])	Likely Causal Relationship (Table 5-17)
Motor Function Decrements	Likely Causal Relationship (Table 5-17)
Adults	
Cognitive Function Decrements (e.g., executive function, visuospatial skills, learning and memory)	Likely Causal Relationship (Table 5-17)
Psychopathological Effects (e.g., symptoms of anxiety and depression)	Likely Causal Relationship (Table 5-17)
Sensory Function Decrements (e.g., hearing threshold)	Suggestive of a Causal Relationship (Table 5-17)
Neurodegenerative Diseases (e.g., Parkinson's disease, Alzheimer's disease)	Inadequate to Infer a Causal Relationship (Table 5-17)

Health Outcome	Causality Determination[a] (Table with Key Supporting Evidence)
Cardiovascular Effects (Section 5.4.7)	
Hypertension	Causal Relationship (Table 5-24)
Subclinical Atherosclerosis (e.g., peripheral artery disease [PAD],intimal media thickness [IMT], atherosclerotic plaque presentation)	Suggestive of a Causal Relationship (Table 5-24)
Coronary Heart Disease (e.g., Heart Rate Variability [HRV], Myocardial Infarction [MI], Ischemic Heart Disease [IHD], cardiovascular mortality; and, in animals, increased thrombosis, coagulation, and arrhythmia)	Causal Relationship (Table 5-24)
Cerebrovascular Disease (e.g., stroke, transient ischemic attack, and subarachnoid hemorrhage)	Inadequate to Infer a Causal Relationship (Table 5-24)
Renal Effects (Section 5.5.5)	
Reduced Kidney Function (e.g., reduced Glomerular Filtration Rate [GFR], reduced creatinine clearance, and increased serum creatinine)	Likely Causal Relationship (Table 5-31)
Immune System Effects (Section 5.6.8)	
Atopic and Inflammatory Responses (e.g., asthma, allergy, Immunoglobulin E [IgE], increased Th2 cytokines)	Likely Causal Relationship (Table 5-34)
Decreased Host Resistance (e.g., antigen responses, effects on macrophages, neutrophil and infection)	Likely Causal Relationship (Table 5-34)
Autoimmunity (e.g., auto-antibodies)	Inadequate to Infer a Causal Relationship (Table 5-34)
Hematologic Effects (Section 5.7.4)	
Decreased Red Blood Cell (RBC) Survival and Function (e.g., Hemoglobin [Hb], Hematocrit [Hct], and mean corpuscular volume [MCV], and measures of oxidative stress)	Causal Relationship (Table 5-35)
Altered Heme Synthesis	Causal Relationship (Table 5-35)
Reproductive and Developmental Effects (Section 5.8.6)	
Development (e.g., delayed onset of puberty, postnatal growth)	Causal Relationship (Table 5-48)
Birth Outcomes (e.g., low birth weight, spontaneous abortion)	Suggestive of Causal Relationship (Table 5-48)
Male Reproductive Function (e.g., sperm parameters)	Causal Relationship (Table 5-48)
Female Reproductive Function (e.g., hormones)	Suggestive of Causal Relationship (Table 5-48)
Cancer (Section 5.10.5)	
Cancer	Likely Causal Relationship (Table 5-50)

[a]Causal determinations were made within approximately 1 order of magnitude of current levels (Preamble, Section 2.1).

2.6.1 Nervous System Effects

The collective body of epidemiologic and toxicological evidence integrated across that reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) coupled with recently available data demonstrates the effects of Pb exposure on a range of nervous system effects. In children, these effects include cognitive function, attention-related behavioral problems, conduct problems, internalizing behaviors, sensory function, and motor function. In adults, nervous system effects examined in relation to Pb exposure include cognitive function, psychopathological effects, sensory function, and neurodegenerative diseases.

2.6.1.1 Children

Cognitive Function Decrements

Multiple prospective studies conducted in diverse populations consistently demonstrate associations of higher blood and tooth Pb levels with lower FSIQ, lower academic performance, and lower performance on tests learning, memory, and executive function. These associations remained after adjustment for a range of potential confounding factors, but most commonly, parental IQ, parental education level, and parental caregiving quality. In school-aged children, associations were found with early childhood, childhood average, and concurrent blood Pb levels and substantiated in populations of children ages 4 to 11 years with mean blood Pb levels between 2 and 8 µg/dL. Uncertainty remains regarding the lifestage of exposure within childhood that is associated with the greatest risk of cognitive function decrements. Observation of a supralinear concentration-response relationship and associations with mean (or quantile) blood Pb levels <4 µg/dL do not provide evidence for a threshold for the cognitive effects of Pb exposure in children. Evidence in children was clearly supported by observations of Pb-induced impairments in learning, memory, and executive function in juvenile animals. Several studies in animals indicated learning impairments with prenatal and early postnatal Pb exposures that resulted in blood Pb levels of 8-26 µg/dL. The mode of action for Pb-associated cognitive impairments is supported by observations of Pb-induced impairments in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and neurotransmitter function. The associations consistently found in prospective studies of children with adjustment for Social Economic Status (SES), parental education and caregiving quality for associations with various indicators of cognitive function and the biological plausibility provided by evidence in animals for impairments in learning, memory, and executive function with relevant Pb exposures and

evidence describing modes of action is sufficient to conclude that there is a causal relationship between Pb exposure and decrements in cognitive function in children.

Attention-Related Behavior Problems

Several prospective studies demonstrate associations of earlier childhood and lifetime average blood Pb levels or tooth Pb levels with inattention, impulsivity, and hyperactivity in children 7-17 years and young adults ages 19-24 years; as assessed using both objective neuropsychological tests and also parent and teacher ratings of behavior. Most studies adjusted for potential confounding by SES and parental caregiving quality, with a few studies also considering substance abuse and nutritional status. Blood Pb-associated increases in attention-related behavioral problems were found in populations with prenatal cord or lifetime average mean blood Pb levels of 6.8 and 14 µg/dL and groups with early childhood blood Pb levels >10 µg/dL. Biological plausibility for observations in children is provided by consistent findings in animals for increases in impulsivity or impaired response inhibition with relevant prenatal and early postnatal Pb exposures that resulted in blood Pb levels of 10 to 31 µg/dL. The mode of action for Pb-associated attention-related behavioral problems is supported by observations of Pb-induced impairments in neurogenesis, synaptic pruning, and dopamine transmission in specific regions of the brain (specifically the prefrontal cerebral cortex, cerebellum, and hippocampus). The consistency of epidemiologic evidence, particularly from prospective studies, and the biological plausibility provided by evidence for Pb-induced impulsivity in animals and for underlying modes of action is sufficient to conclude that there is a causal relationship between Pb exposure and attention-related behavioral problems in children.

Internalizing Behaviors

Prospective studies in a few populations demonstrate associations of higher lifetime average blood or childhood tooth Pb levels with higher parent and teacher ratings of internalizing behaviors such as depression, anxiety, and withdrawn behavior in school-aged children. The lack of selective participation by blood Pb level and associations found with parental and teacher ratings do not provide strong indication of biased reporting of behaviors for children with higher blood Pb levels. While results were adjusted for maternal education and SES-related variables, consideration for potential confounding by parental caregiving quality was inconsistent. The biological plausibility for the effects of Pb on internalizing behaviors is provided by consistent findings in animals, with some evidence at blood Pb levels relevant to humans and by evidence supporting modes of action, including Pb-induced changes in the Hypothalmic-Pituitary-

Adrenal (HPA) axis and dopaminergic and GABAergic systems.HPA axis and dopaminergic and GABAergic systems. The evidence from prospective studies in a few populations and the supporting toxicological evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and internalizing behaviors.

Conduct Problems in Children and Young Adults

Prospective studies consistently indicate that early childhood or lifetime average blood Pb levels or tooth Pb levels are associated with criminal offenses in young adults ages 19-24 years and with higher parent and teacher ratings of misconduct in children ages 7-17 years. These associations were found without any indication of strong selection bias and with adjustment for SES, parental education and IQ, parental caregiving quality, family functioning, smoking, and substance abuse. Supporting evidence is provided by cross-sectional evidence of children participating in NHANES and a meta-analysis of prospective and cross-sectional studies. Evidence for Pb-induced aggression in animals is mixed. The consistent epidemiologic evidence from prospective and cross-sectional studies for criminal offenses and ratings of misconduct but lack of clear evidence for aggression in animals is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and misconduct in children and young adults.

Sensory Function Decrements

Evidence from prospective and cross-sectional studies in a few populations indicates associations of higher blood Pb levels with increases in hearing thresholds and decreases in auditory evoked potentials after adjustment for several potential confounding factors, including SES, parental caregiving quality, and child health. The high participation rates, particularly in a prospective study with follow-up from birth, reduce the likelihood of biased participation of children with higher blood Pb levels. Findings in animals indicate that dietary Pb exposure increases hearing thresholds and latencies for auditory evoked potentials; however, studies examined higher Pb exposures than those relevant to humans. The evidence in children, particularly from prospective studies, with consideration for potential confounding by factors such as SES, parental caregiving quality, child health, and nutritional factors, is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and decrements in sensory function in children.

Motor Function Decrements

Evidence from prospective and cross-sectional studies in a few populations indicates associations of higher blood Pb level with decrements in fine and gross motor function with adjustment for several potential confounding factors, including SES, parental caregiving quality, and child health. The high participation rates, particularly in prospective studies with follow-up from birth or early infancy, reduce the likelihood of biased participation of children with higher blood Pb levels. The biological plausibility for associations observed in children is provided by observations of poorer balance in male mice with relevant Pb exposures. The evidence in children, particularly from prospective studies, and the coherence with findings in mice is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and decrements in motor function.

2.6.1.2 Adults

Cognitive Function

In adults without occupational exposure, prospective studies in the Normative Aging Study (NAS) and Baltimore Memory Study (BMS) cohorts indicate associations of higher tibia Pb levels with declines in cognitive function over 2- to 4-year periods. While the specific factors differed between studies, these tibia Pb-associated cognitive function decrements were found with adjustment for potential confounding factors such as age, education, SES, alcohol use, and smoking. Supporting evidence is provided by cross-sectional studies finding stronger associations with bone Pb level than concurrent blood Pb level, with more extensive consideration for potential confounding factors, including dietary factors, physical activity, medication use, and comorbid conditions. The specific timing, frequency, duration, and magnitude of Pb exposures contributing to the associations observed with bone Pb levels are uncertain. Also uncertain is the residual confounding by age. Associations between blood Pb levels and cognitive function decrements found in adults with occupational Pb exposures provide evidence for the effects of current Pb exposures, although these studies did not consider potential confounding by other workplace exposures. The biological plausibility for the effects of Pb exposure on cognitive function decrements in adults is provided by findings that lifetime or postnatal Pb exposure induces learning impairments in adult animals and by evidence supporting modes of action. The associations between bone Pb level and cognitive function decrements consistently found in the few prospective and cross-sectional studies of adults without occupational Pb exposure, the coherence with animal findings, and evidence supporting mode of action are sufficient to conclude that a causal

relationship is likely to exist between long-term cumulative Pb exposure and cognitive function decrements in adults.

Psychopathological Effects

Cross-sectional studies in a few populations demonstrate associations of higher concurrent blood or tibia Pb levels with self-reports of depression and anxiety symptoms in adults. The examination of multiple exposures and outcomes in the available studies does not provide strong indication of biased reporting of effects by adults with higher Pb exposures. In adults, Pb-associated increases in self-reported depression and anxiety were found with adjustment for age, SES, and in the NAS, daily alcohol intake. The biological plausibility for the effects of Pb on depression is provided by observations of depression-like behavior in animals, with some evidence at blood Pb levels relevant to humans and by evidence supporting modes of action, including Pb-induced changes in the HPA axis and dopaminergic and GABAergic systems. Although the frequency, timing, level and duration of exposure contributing to the observed associations is uncertain, the evidence from a few populations in adults and the supporting toxicological evidence are sufficient to conclude that a causal relationship is likely to exist between Pb exposure and psychopathological effects in adults.

Sensory Function Decrements

Evidence was provided by the prospective analysis of the Normative Aging Study of the U.S. Department of Veteran's Affairs (NAS) men, for associations of higher tibia Pb level with a greater rate of elevations in hearing threshold. Biological plausibility was provided by the evidence for Pb-induced decreases in auditory evoked potentials in animals, albeit at higher blood Pb levels than those relevant to humans. Taken together, the evidence is suggestive of a causal relationship between Pb exposure and sensory function decrements in adults.

Neurodegenerative Disease

While evidence is inconclusive for Amyotrophic Lateral Sclerosis (ALS)and Alzheimer's disease, a few case-control studies each found higher blood Pb levels in adults with essential tremor and higher bone Pb levels in adults with Parkinson's disease. Because of the inconclusive evidence for some diseases and limitations such as reverse causality for essential tremor and the lack of consideration for potential confounding by manganese (Mn) exposure for both essential tremor and Parkinson's disease, the evidence is

inadequate to determine that there is a causal relationship between Pb exposure and neurodegenerative diseases.

2.6.2 Cardiovascular Effects

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that there was a relationship between higher blood Pb and bone Pb and cardiovascular effects in adults, in particular increased BP and increased incidence of hypertension , and recent evidence strengthens this conclusion. For the evaluation of causal relationships with Pb exposure, evidence was grouped in categories using the U.S. Surgeon General's Report on Smoking as a guideline (CDC, 2004). The categories include hypertension (Section 5.4.7.1), subclinical atherosclerosis (Section 5.4.7.2), coronary heart disease (Section 5.4.7.3), and cerebrovascular disease (Section 5.4.7.4).

Hypertension

Evidence from epidemiologic and toxicological studies demonstrates consistent effects of Pb exposure on hypertension. Longitudinal prospective studies clearly support the association of biomarkers of Pb exposure with hypertension incidence and increased BP. These high quality studies provide evidence that is replicated across a large number of studies with different designs, populations, and locations (Section 5.4.2 and Section 5.4.7.1). Meta-analyses of Pb-associated increases in BP and hypertension indicate consistency in the strength of associations across studies (Navas-Acien et al., 2008; Nawrot et al., 2002) found that each doubling of concurrent blood Pb level (between 1 and >40 µg/dL) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP. Navas-Acien et al. (2008) found that all studies included in the meta-analysis showed a relationship between higher bone Pb levels, which is a marker of cumulative exposure, and higher BP.

Further support for a causal relationship between blood and bone Pb levels and increased BP and hypertension is provided by a multiple cross-sectional analyses [e.g., (Martin et al., 2006; Muntner et al., 2005)]. Despite the extensive evidence for associations at relatively low concurrent blood Pb levels, these cardiovascular outcomes were most often examined in adults that were exposed to higher levels of Pb earlier in life, and uncertainty remains concerning the Pb exposure level, timing, frequency, and duration contributing to the observed effects; however, the majority of animal toxicological studies provide support for the effects of long-term Pb exposure on BP in a range that is relevant to humans 10 -30 µg/dL (Figure 5-21). Prospective epidemiologic studies, in conjunction with these animal toxicology studies, also demonstrate the temporal relationship between

the exposure and effect. Evidence for Pb-induced hypertension and increased BP is further supported by prospective epidemiologic studies showing consistent associations between Pb biomarkers and related conditions including cardiovascular and all-cause mortality (Section 5.4.5). Animal toxicology studies further indicate coherence and strengthen the evidence for causality by providing evidence of biological plausibility (e.g., oxidative stress and contractile processes) for the effect of Pb exposure on the risk of increased BP and hypertension.

While the control for specific potential confounders varied by study, factors including age, diet, sex, body mass index (BMI), blood pressure lowering medication use, SES, race/ethnicity, alcohol consumption, cholesterol, smoking, pre-existing disease (i.e., diabetes), measures of renal function, and copollutant exposures (i.e., cadmium [Cd]) were considered. Although no single study adjusted for all potential confounders and residual confounding by age may be present in studies using bone Pb measurements, uncertainties related to confounding bias are reduced with consideration of other lines of evidence that demonstrate the long term effects of Pb in animals and characterize biologically plausible modes of action. Overall, evidence in epidemiologic of adults and experimental studies in animals demonstrates the effect of long-term Pb exposure in increasing BP and hypertension although uncertainty remains concerning the relevant Pb exposure patterns contributing to the observed effects. Overall the evidence is sufficient to conclude that there is a causal relationship between Pb exposure and hypertension.

Subclinical Atherosclerosis

A limited number of studies have evaluated markers of subclinical atherosclerosis following Pb exposure in humans or animals. Epidemiologic findings are limited to cross-sectional analyses. One previous NHANES analysis reported an association between Pb and peripheral artery disease (PAD) that was not confounded by cadmium (Cd) (Navas-Acien et al., 2004). Another study reported an increasing trend in the odds of PAD, which is an indicator of atherosclerosis, and concurrent blood Pb level in adults within the NHANES population (Muntner et al., 2005). Although evidence of plausible biological mechanisms (e.g., oxidative stress, inflammation, endothelial cell dysfunction) is clearly described in the animal toxicological literature, these studies have provided limited evidence to suggest Pb exposure may initiate atherosclerotic vessel disease. Further, uncertainty remains concerning the Pb exposure level, timing, frequency, and duration contributing to the observed association with PAD. The evidence is suggestive of a causal relationship between Pb exposure and subclinical atherosclerosis.

Coronary Heart Disease

There was a small number of studies discussed in the 2006 Pb AQCD (U.S. EPA, 2006b) that indicated associations between Pb biomarker levels and increased risk of coronary heart disease (CHD) endpoints. Recent longitudinal prospective studies that consistently report that blood Pb level is associated with risk of mortality from cardiovascular disease, specifically MI, IHD, or CHD (Figure 5-30 and Table 5-23) support and expand upon this body of evidence. In addition, Weisskopf et al. (2009) found that patella bone Pb levels were associated with increased mortality from IHD (similar magnitude non-statistically significant associations were observed with tibia Pb levels) among subjects enrolled in the NAS. Several recent studies also report associations between biomarkers of Pb and incidence of CHD-related outcomes including a prospective analysis reporting an increased incidence of IHD (physician confirmed MI, angina pectoris) with blood and bone Pb levels (Jain et al., 2007). Uncertainty remains regarding the level, timing, frequency, and duration of Pb exposure contributing to CHD in adult populations with higher past than recent exposure. However, coherence for the associations in humans is supported by the observation of thrombus formation in animals after long term exposure (Sections 5.4.7.3 and 5.4.3) and mode of action for Pb-induced CHD (i.e., hypertension, HRV, increased corrected QT (QTc) interval, and corrected QRS complex (QRSc) duration in electrocardiogram [ECG]) in humans and animals (Sections 5.4.2 and 5.4.3.4). The overall evidence is sufficient to conclude that there is a causal relationship between Pb exposure and coronary heart disease.

Cerebrovascular Disease

Both hypertension and atherosclerosis are risk factors for cerebrovascular disease and the mechanisms for these outcomes also apply to cerebrovascular disease. Despite strong evidence for hypertension and CHD and Pb exposure, very few studies have examined the effects of Pb exposure on cerebrovascular disease (Section 5.4.7). These few studies provide insufficient evidence to inform the presence or absence of a causal relationship between cerebrovascular disease and Pb exposure. Thus, the current evidence is inadequate to determine that a causal relationship exists between Pb exposure and cerebrovascular disease.

2.6.3 Renal Effects

Recent epidemiologic and toxicological studies evaluated in the current review support and expand upon the strong body of evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006b) indicating that Pb exposure is associated with reduced kidney function (Section 5.5.5). The causal determination for reduced kidney function is informed by evidence for reduced GFR, reduced creatinine clearance, and increased serum creatinine.

Reduced Kidney Function

The epidemiologic evidence from prospective and cross-sectional studies consistently demonstrates a relationship between higher blood Pb level and reduced kidney function (e.g., lower creatinine clearance, higher serum creatinine, and lower GFR) in nonoccupationally-exposed adults with mean concurrent or baseline blood Pb levels of 2-10 µg/dL. Associations were observed after adjustment for multiple potential confounding factors such as age, sex, comorbid cardiovascular conditions, BMI, smoking, and alcohol use. However, uncertainties involve the potential for reverse causality to play a role in the findings of cross-sectional studies and inconsistent findings in occupational studies. Further, since the blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations is also uncertain. A few analyses find higher blood Pb levels to be associated with a greater longitudinal decrease in kidney function over time (4-15 years), suggesting that past Pb exposures may contribute to ongoing renal effects and better characterizing the time sequence between Pb exposure and lower kidney function. Studies in animals with long-term exposure to Pb report mixed evidence for Pb-induced kidney dysfunction and histopathological changes, including tubular atrophy and sclerosis at relevant Pb blood and exposure levels. Animal studies provide biological plausibility for the associations observed in epidemiologic studies between blood Pb levels and reduced kidney function with evidence for Pb-induced hypertension, renal oxidative stress, inflammation, apoptosis, and glomerular hypertrophy. The body of the evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and reduced kidney function.

2.6.4 Immune System Effects

The cumulative body of epidemiologic and toxicological evidence from the 2006 Pb AQCD (U.S. EPA, 2006b) and the current assessment describes several effects of Pb exposure on the immune system related to a shift from T-derived lymphocyte helper (Th)1 - to T-derived lymphocyte helper (Th)2 -type responses, including an increase in atopic and inflammatory conditions and a decrease in host resistance (Section 5.6.8). Outcomes related to an increase in atopic and inflammatory conditions include asthma, allergy, increased IgE, and mode of action endpoints such as selective differentiation of Th2 cells, increased production of Th2 cytokines, B cell activation, and inflammation. Outcomes related to decreased host resistance include enhanced susceptibility to bacterial and viral infection, suppressed delayed type hypersensitivity (DTH), and those describing mode of action, i.e., decreased production of Th1 cytokines, reduced phagocyte function, and increased inflammation. A small body of studies indicates the effects of Pb exposure on autoimmunity.

Atopic and Inflammatory Conditions

Prospective studies in a few populations of children indicate associations of blood Pb levels with asthma and allergy, with a cross-sectional study providing supporting evidence (Section 5.6.5.2). Prospective design, lack of selective participation of subjects, and objective assessment of outcomes reduce the likelihood that findings are explained by selection bias or reverse causality. Several studies consider potential confounding by SES and exposure to smoking or allergens. Although adjustment for these factors increases confidence that the observed associations reflect an independent association with Pb exposure, the potential for residual confounding by factors such as SES remains. However, the evidence for asthma and allergy is supported by associations found between higher concurrent blood Pb levels in children and higher IgE, an important mediator of asthma and allergy. In addition, biological plausibility for the effects of Pb on IgE is provided by consistent findings in animals (i.e., Pb-induced increases in Th2 cytokine production and inflammation), with some evidence at blood Pb levels relevant to humans. In epidemiologic studies, higher IgE and higher asthma prevalence were examined and found in children with concurrent blood Pb levels >10 µg/dL. The strong toxicological evidence from experimental animal studies supporting modes of action for a shift to a Th2 phenotype combined with the epidemiologic evidence for asthma and allergy in a few populations is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and an increase in atopic and inflammatory conditions.

Decreases in Host Resistance

Much of the evidence on decreased host resistance was available in the 2006 Pb AQCD (U.S. EPA, 2006b) and summarized in Section 5.6.5.1 (and Section 5.6.8.2). Decreased host resistance is demonstrated by several toxicological observations that dietary Pb exposure producing relevant blood Pb levels increased susceptibility to bacterial infection and suppressed DTH in rodents and by the coherence with evidence describing modes of action, including suppressed production of Th1 cytokines and decreased macrophage function. Animal studies found that gestational Pb exposures, producing blood Pb levels of 6 and 25 µg/dL, resulted in decreases in Th1 cytokines, suppression of DTH, and greater susceptibility to bacterial infection. However, these effects related to decreased host resistance also were affected by neonatal short-term (several days to 2-3 weeks), long-term (>4 weeks), and lifetime Pb exposures that produced blood Pb levels 1-25 µg/dL. Thus, the toxicological evidence does not clearly identify a particular lifestage of Pb exposure that is more strongly associated with decreased host resistance. Epidemiologic evidence indicates Pb-associated increases in respiratory infections but limitations, including the lack of rigorous methodology and consideration for potential confounding produce uncertainty regarding the effects of Pb on decreased host resistance in humans. The consistent toxicological evidence but lack of available informative epidemiologic evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and decreased host resistance.

Autoimmunity

Toxicological evidence indicates the potential of Pb to increase autoimmunity, with a few previous studies showing Pb-induced generation of auto-antibodies (discussed in the 2006 Pb AQCD), and with recent studies providing indirect evidence by showing formation of neoantigens that could result in the formation of auto-antibodies (Sections 5.6.5.4 and 5.6.8.3). Several observations were made in animals injected with Pb, which is a route of exposure with less relevance to humans. Higher levels of auto-antibodies also were found in Pb-exposed battery workers; however, implications are limited because of the high blood Pb levels (range: 10-40 µg/dL) of some of the workers and lack of consideration for potential confounding by several factors, including other occupational exposures. Because results from available toxicological and epidemiologic studies do not sufficiently inform Pb-induced generation of auto-antibodies with relevant Pb exposures, the evidence is inadequate to determine if there is a causal relationship between Pb exposure and autoimmunity.

2.6.5 Hematological Effects

Recent toxicological and epidemiologic evidence substantiates evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006b) that exposure to Pb affects hematological endpoints, and supports a causal relationship between Pb exposure and decreased red blood cell (RBC) survival and function and altered heme synthesis. Outcomes related to decreased RBC survival and function included alterations in multiple hematological parameters (e.g., Hb, Hct, MCV), oxidative stress (altered antioxidant enzyme activities, decreased cellular glutathione (GSH), and increased lipid peroxidation), increased cytotoxicity in RBC precursor cells, and mode of action endpoints such as decreased intracellular calcium concentrations $[Ca^{2+}]_i$, decreased adenosine-triphosphase (ATPase) activity, and increased phosphatidylserine expression. Outcomes related to altered heme synthesis included decreased activities of ALAD and ferrochelatase, and decreased levels of Hb.

Decreased Red Blood Cell Survival and Function

Experimental animal studies demonstrate that exposures via drinking water and gavage, resulting in blood Pb levels relevant to humans, alter several hematological parameters, increase measures of oxidative stress and increase cytotoxicity in red blood cell (RBC) precursor cells. Support for these findings is provided by biologically plausible modes of action including decreased intracellular calcium concentrations $[Ca^{2+}]_i$, decreased ATPase activity, and increased phosphatidylserine expression. Epidemiologic studies demonstrate evidence in both adults and children that Pb exposure results in altered hematological endpoints and increased measures of oxidative stress, and altered hematopoiesis. Although the majority of these studies are limited by the lack of rigorous methodology and consideration for potential confounding they support the toxicological findings. While some studies in children did control for or considered potential confounding and effects in adults and children are coherent with effects observed in exposed animals, there remains some uncertainty regarding the evidence for altered RBC survival and function in human populations. Collectively, the strong evidence from toxicological studies that is supported by findings from mode of action and epidemiologic studies is sufficient to conclude that there is a causal relationship between Pb exposures and decreased RBC survival and function.

Heme Synthesis

Altered heme synthesis is demonstrated by a small, but consistent, body of experimental animal studies reporting that exposures via drinking water and gavage (resulting in blood Pb levels relevant to humans) decreased ALAD and ferrochelatase activities. Supporting

this toxicological evidence is a larger body of ecotoxicological studies that demonstrate decreased ALAD activity across a wide range of taxa exposed to Pb. Epidemiologic studies demonstrate evidence in both adults and children that Pb exposure results in decreased ALAD and ferrochelatase activities. However, the majority of these studies are limited by the lack of rigorous methodology and consideration for potential confounding. While some studies in children did control for or considered potential confounding and effects in adults and children are coherent with effects observed in exposed animals, there remains some uncertainty regarding the evidence for altered heme synthesis in human populations. Evidence for altered heme synthesis is also provided by a large body of toxicological and epidemiologic studies that report decreased Hb concentrations due to Pb exposure. Collectively, the strong evidence from toxicological and ecotoxicological studies that is supported by findings from epidemiologic studies is sufficient to conclude that there is a causal relationship between Pb exposures and altered heme synthesis.

2.6.6 Reproductive and Developmental Effects

Many epidemiologic and toxicological studies of the effects of Pb on reproductive and developmental outcomes have been conducted since the 2006 Pb AQCD. The evaluation of causal relationships with Pb exposure focuses on four areas: developmental effects, birth outcomes, reproductive function among males, and reproductive function among females.

Development

The 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb-associated effects on development in toxicological studies. Findings from epidemiologic studies of postnatal growth are inconsistent and findings from animal toxicological studies are mixed, with recent studies on the effect of Pb on growth showing Pb to elicit adult onset obesity. Multiple recent epidemiologic studies of Pb and puberty have shown associations between concurrent blood Pb levels and delayed pubertal onset for girls and boys. In cross-sectional epidemiologic studies of girls (ages 6-18 years) with mean and/or median concurrent blood Pb levels less than 5 µg/dL consistent associations with delayed pubertal onset were observed. In boys (ages 8-15 years), fewer epidemiologic studies were conducted but associations were observed, including associations among boys in a longitudinal study. These associations are consistently observed in populations with blood Pb levels <10µg/dL; however, there is uncertainty with regard to the exposure frequency, timing, duration and level contributing to the observed effects in studies of older children and adolescents. The evidence of delayed pubertal onset among males and females from

epidemiologic studies is consistent and coherent with evidence from toxicological studies at relevant exposure levels. Potential confounders considered in the epidemiologic studies varied. Most studies controlled for age and body mass index (BMI). Other variables, such as measures of diet, SES, and race/ethnicity, were included in some of the studies. Although, adjustment for nutritional factors was done less often, a NHANES analysis of girls (Selevan et al., 2003) controlled for various dietary factors as well as other potential confounders and reported an association between increased blood Pb levels and delayed pubertal onset. Overall, the toxicological and epidemiologic evidence together is sufficient to conclude that there is a causal relationship between Pb exposure and developmental effects.

Birth Outcomes

Overall, results of pregnancy outcomes were similar to those of the 2006 Pb AQCD (U.S. EPA, 2006b); no consistent evidence of a relationship with Pb was available for preterm birth. The 2006 Pb AQCD included a few studies that reported potential associations between Pb and neural tube defects, but the recent epidemiologic studies found no association (Section 5.8.6.2). Some associations were observed between Pb and low birth weight when epidemiologic studies used measures of maternal bone Pb or air exposures. The associations were less consistent when using maternal blood Pb or umbilical cord and placenta Pb, but some associations between increased Pb levels and decreased low birth weight/fetal growth were observed. The effects of Pb exposure during early development in animal toxicological studies included mixed findings with some studies showing reduction in litter size, implantation, and birth weight. Based on the observation of some associations observed in well-conducted epidemiologic studies of preterm birth and low birth weight/fetal growth, the evidence is suggestive of a relationship between Pb exposure and birth outcomes.

Male Reproductive Function

Evidence from recent experimental studies of animals and supporting evidence from epidemiologic studies expands upon findings from the 2006 Pb AQCD to indicate that a causal relationship exists between Pb exposure and male reproductive function. Toxicological studies in rodents, non-human primates, and rabbits show detrimental effects on semen quality, sperm, and fecundity/fertility epidemiologic studies report detrimental effects on sperm. The effect of Pb on other aspects of male reproduction, including hormone aberrations is less clear. Findings from epidemiologic studies of fertility among men were also mixed. Pb may exert effects on the reproductive system by affecting the responsiveness of the hypothalamic-pituitary-gonad axis or by suppressing

circulating hormone levels. Recent toxicological studies suggest that oxidative stress is a major contributor to the effects of Pb on male reproductive system, providing mode of action support. The effects of reactive oxygen species (ROS) may involve interference with cellular defense systems leading to increased lipid peroxidation and free radical attack on lipids, proteins, and DNA. Several recent studies showed Pb induced an increased generation of ROS within the male sex organs and germ cell injury as evidenced by aberrant germ cell structure and function. Co-administration of Pb with various antioxidant compounds either eliminated Pb-induced injury or greatly attenuated its effects. In addition, many studies that observed increased oxidative stress also observed increased apoptosis which is likely a critical underlying mechanism in Pb-induced germ cell DNA damage and dysfunction. Based on the consistency and coherence of findings for effects of Pb exposure on sperm in the toxicological literature, and the support from epidemiologic studies with biological plausibility provided by mode of action evidence, the evidence is sufficient to conclude that there is a causal relationship between Pb exposures and male reproductive function.

Female Reproductive Function

Epidemiologic and toxicological studies of reproductive function among females investigated whether Pb biomarker levels were associated with hormone levels, fertility, estrus cycle changes, and morphology or histology of female reproductive organs including the placenta (Section 5.8.6.4). Toxicological studies of experimental animals reported in the 2006 Pb AQCD (U.S. EPA, 2006b) demonstrated associations between Pb exposure and female reproductive function, although little evidence was provided by epidemiologic studies. Some studies have shown associations with blood Pb levels and altered hormone levels in adults, with inconsistency across studies likely due to the different hormones examined and the different timing in the menstrual and life cycles. There is some evidence of a potential relationship between Pb exposure and female fertility, but findings are also mixed. The majority of the epidemiologic studies are cross-sectional, and adjustment for potential confounders varies from study to study, with some potentially important confounders, such as BMI, not included in all studies. Also, most of the studies have small samples sizes and are generally of women attending infertility clinics. The design of animal toxicological studies often employs prenatal or early postnatal Pb exposures with Pb contributing to placental pathology and inflammation, decreased ovarian antioxidant capacity, altered ovarian steroidogenesis and aberrant gestational hormone levels. Although epidemiologic and toxicological studies provide information on different exposure periods, both types of studies support the conclusion that Pb possibly affects at least some aspects of female reproductive function. Overall, the relationship observed with female reproductive outcomes is sufficient to

conclude that there is a suggestive relationship between Pb exposure and female reproductive function.

2.6.7 Cancer

The toxicological literature from experimental animal studies provides the strong evidence for Pb exposure and cancer. The consistent evidence indicating Pb-induced carcinogenicity in animal models is substantiated by the mode of action findings from multiple high-quality studies from different laboratories. This conclusion is in agreement with those of other agencies including the International Agency for Research on Cancer (IARC, which has classified inorganic Pb compounds as a probable human carcinogen), and the National Toxicology Program (NTP, which has listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens"). Strong evidence from animal toxicological studies demonstrates an association between Pb and cancer, genotoxicity, mutagenicity or epigenetic modification. Carcinogenicity in animal toxicology studies with relevant routes of Pb exposure has been reported in the kidneys, testes, brain, adrenals, prostate, pituitary, and mammary gland (Table 5-50). Epidemiologic studies of cancer incidence and mortality reported inconsistent results; one strong epidemiologic study demonstrated an association between blood Pb and increased cancer mortality, but the other studies reported weak or no associations. In the 2006 Pb AQCD (U.S. EPA, 2006b), Pb exposure was found to be associated with stomach cancer, and a recent study on stomach cancer and Pb exposure, reported mixed findings depending on the type of Pb exposure (organic Pb, inorganic Pb, or Pb from gasoline emissions). Similarly, some studies in the 2006 Pb AQCD reported associations between Pb exposure and lung cancer. Recent epidemiologic studies of lung cancer focused on occupational exposures and reported inconsistent associations. The majority of epidemiologic studies of brain cancer had null results overall, but positive associations between Pb exposure and brain cancer were observed among individuals with certain genotypes. Overall, despite the inconsistent findings from epidemiologic studies, the consistent and strong body of evidence from toxicological studies is sufficient to conclude that there is a likely causal relationship between Pb exposure and cancer.

2.7 Ecological Effects of Pb

Sections 2.7.1 and 2.7.2 are summaries of the evidence evaluated in Chapter 7 in which the effects of Pb on terrestrial and aquatic ecosystems are presented separately. The evidence supporting ecological causal determinations is synthesized across endpoints (reproduction, growth, survival, neurobehavioral effects, hematological effects, physiological stress) common to terrestrial, freshwater and saltwater biota in Section 2.7.3 (Table 2-3). An integration of the evidence across endpoints examined in both human health and ecological studies follows (Section 2.8). Consideration of atmospheric deposition of Pb as related to ecological effects is discussed under policy relevant considerations (Section 2.9.7).

2.7.1 Summary of Effects on Terrestrial Ecosystems

Historically, Pb poisoning is one of the earliest recognized toxicoses of terrestrial biota, occurring primarily through ingestion of spent shot by birds (Section 7.3.4.3). At the time of the 1977 Pb AQCD, few studies of Pb exposure and effects in wild animals other than birds were available. A limited number of rodent trapping studies and observations from grazing animals near smelters provided evidence for differences in Pb sensitivity among species and these findings were further supported in the 1986 and 2006 Pb AQCDs (U.S. EPA, 2006b, 1986b, 1977). Commonly observed effects of Pb on terrestrial organisms include decreased survival, reproduction, and growth, as well as effects on development, behavior, and ALAD activity (U.S. EPA, 2006b, 1986b, 1977).

In plants, Pb effects have been studied for several decades. At the time of the 1977 Pb AQCD, it was understood that Pb uptake in plants was influenced by plant species and by the available Pb pool in the soils, and that most of the Pb taken up by plants from soil remains in the roots, with translocation to other portions of the plant varying with species (U.S. EPA, 1977). Plant growth was recognized as an endpoint of Pb toxicity in plants in the 1977 Pb AQCD and additional effects of Pb on growth processes were reported in subsequent Pb AQCDs (U.S. EPA, 2006b, 1986b, 1977). In the 1977 Pb AQCD evidence for effects of Pb on forest-nutrient cycling and shifts in arthropod community composition was found in one study conducted in the vicinity of a smelting complex. In subsequent AQCDs, other ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation have subsequently been reported near stationary sources of Pb (U.S. EPA, 2006b, 1986b, 1977; Watson et al., 1976).

Pb is either deposited directly onto plant surfaces, or soil where it can bind with organic matter or dissolve in pore water. The amount of Pb dissolved in soil pore water determines the impact of soil Pb on terrestrial ecosystems to a much greater extent than the total amount present. It has long been established that the amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds; (3) adsorption-desorption reactions of dissolved Pb phases on soil organic matter; (4) pH; (5) cation exchange capacity (CEC); and (6) aging. Since 2006, further details have been contributed to the understanding of the role of pH, CEC, organic matter, and aging. Smolders et al. (2009) demonstrated that the two most important determinants of both Pb solubility and toxicity in soils are pH and CEC. However, they had previously shown that experimental aging, primarily in the form of initial leaching following addition of Pb, decreases soluble metal fraction by approximately one order of magnitude (Smolders et al., 2009). Since 2006, organic matter has been confirmed as an important influence on Pb sequestration, leading to longer-term retention in soils with higher organic matter content, and also creating the potential for later release of deposited Pb. Aging, both under natural conditions and simulated through leaching, was shown to substantially decrease bioavailability to plants, microbes, and vertebrates.

Evidence over several decades of research, previously reviewed in Pb AQCDs and in more recent studies, shows that Pb accumulates in terrestrial plants, invertebrates and vertebrates. Studies with herbaceous plant species growing at various distances from smelters added to the existing strong evidence that atmospherically transported Pb is taken up by those plants. In most species tested, soil Pb taken up by the roots is not translocated into the stem and leaves. These studies did not establish the relative proportion that originated from atmospheric Pb deposited in the soil, as opposed to that taken up directly from the atmosphere through the leaves. In trees, studies have found that soil Pb generally is translocated to other parts, in contrast to herbaceous plants, and recent studies have shown that the proportion of Pb that is taken up through the leaves and trunk is likely substantial. One study attempted to quantify this proportion Pb that is taken up directly from the atmosphere suggested it amounts to 50% of the Pb contained in Scots pine (*Pinus sylvestris*) in Sweden (Klaminder et al., 2005).

Since the 2006 Pb AQCD, various species of terrestrial snails have been found to accumulate Pb from both diet and soil. Recent studies with earthworms have found that both internal concentration of Pb and mortality increase with decreasing soil pH and CEC, and the importance of the interaction of those factors with Pb concentration has been strongly confirmed, but only very partially quantified. Tissue concentration differences have been found between species of earthworms that burrow in different soil layers, and the rate of accumulation in each of these species may result from differences

in interacting factors such as pH and CEC between layers. Because earthworms often sequester Pb in granules, some authors have suggested that earthworm Pb is not bioavailable to their predators. There is some evidence that earthworm activity increases Pb availability in soil, but it is inconsistent. In various arthropods collected at contaminated sites, recent studies found gradients in accumulated Pb that corresponded to gradients in soil with increasing distance from stationary sources.

There are a few recent studies of Pb bioavailability and uptake in birds since the 2006 Pb AQCD. Several found tissue levels in birds that indicated exposure to Pb, but none of the locations for these studies was in proximity to stationary sources, and the origin of the Pb could not be identified. A study at the Anaconda Smelter Superfund site found increasing Pb accumulation in gophers with increasing soil Pb around the location of capture. A study of swine fed various Pb-contaminated soils showed that the form of Pb determined accumulation. Recent studies were able to measure Pb in the components of various food chains that included soil, plants, invertebrates, and vertebrates. They confirmed that trophic transfer of Pb is pervasive, but no consistent evidence of trophic magnification was found.

Evidence in this review further supports the findings of the previous Pb AQCDs that biological effects of Pb on terrestrial organisms vary with species and lifestage, duration of exposure, form of Pb, and soil characteristics. In photosynthetic organisms, experimental studies have added to the existing evidence of photosynthesis impairment in plants exposed to Pb, and have found damage to photosystem II due to alteration of chlorophyll structure, as well as decreases in chlorophyll content in diverse taxa, including lichens and mosses. Evidence of oxidative stress in response to Pb exposure has also been observed in plants. Reactive oxygen species were found to increase in broad bean and tomato plants exposed to increasing concentrations of soil Pb, and a concomitant increase in superoxide dismutase, glutathione, peroxidases, and lipid peroxidation, as well as decreases in catalase were observed in the same plants. Monocot, dicot, and bryophytic taxa grown in Pb-contaminated soil or in experimentally spiked soil all responded to increasing exposure with increased antioxidant activity. In addition, reduced growth was observed in some experiments, as well as genotoxicity, decreased germination, and pollen sterility.

In terrestrial invertebrates, evidence for Pb effects has included neurological and reproductive endpoints. Recently published studies have shown neuronal damage in nematodes exposed to concentrations of Pb [2.5 μM (0.5 mg Pb/L)] in laboratory settings, accompanied by behavioral abnormalities. Reproductive adverse effects were found at lower exposure in younger nematodes, and effects on longevity and fecundity were shown to persist for several generations. Increased mortality was found in earthworms,

but was strongly dependent on soil characteristics including pH, CEC, and aging. Snails exposed to Pb through either topical application or through consumption of Pb-exposed plants had increased antioxidant activity, and decreased food consumption, growth, and shell thickness. Effects on arthropods exposed through soil or diet varied with species and exposure conditions, and included diminished growth and fecundity, endocrine and reproductive anomalies, and body malformations. Within each study, increasing concentration of Pb in the exposure medium generally resulted in increased effects, but the relationship between concentration and effects varied between studies, even when the same medium, e.g., soil, was used. Evidence suggested that aging and pH are important modifiers.

ALAD was identified in the 1977 Pb AQCD as a sensitive indicator of exposure to Pb in rats and waterfowl, and became regarded as a biomarker of exposure in many terrestrial vertebrates. Other effects of Pb on vertebrates reviewed in Pb AQCDs and the current document include decreased white blood cell counts and behavioral anomalies observed in amphibians and reptiles. However, large differences in effects were observed at the same concentration of Pb in soil, depending on whether the soil was freshly amended or field-collected from contaminated areas. As in most studies where the comparison was made, effects were smaller when field-collected soils were used. In some birds, maternal elevated blood Pb level was associated in recent studies with decreased hatching success, smaller clutch size, high corticosteroid level, and abnormal behavior. Some species evidenced little or no effect of elevated blood Pb level. Effects of dietary exposure were studied in several mammalian species, and cognitive, endocrine, immunological, and growth effects were observed.

Recent evidence reviewed in Sections 7.3.6 and 7.3.12.7 demonstrates that exposure to Pb is generally associated with negative effects in terrestrial ecosystems. It also demonstrates that many factors, including species and various soil physiochemical properties, interact strongly with Pb concentration to modify those effects. In these ecosystems, where soil is generally the main component of the exposure route, Pb aging is a particularly important factor, and one that may be difficult to reproduce experimentally. Without quantitative characterization of those interactions, characterizations of exposure-response relationships would likely not be transferable outside of experimental settings. Since the 2006 Pb AQCD, few studies of exposure-response have been conducted, and results have been inconsistent.

Recent evidence of effects of Pb at the community and ecosystem levels of biological organization include several studies of the ameliorative effects of mycorrhizal fungi on plant growth in the presence of Pb, attributed to decreased uptake of Pb by plants, although both mycorrhizal fungus and plant were negatively affected at the exposures

assessed. Most recently published research on community and ecosystem-level effects of Pb has focused on soil microbial communities, which have been shown to be impacted in both composition and activity. Many of the recent studies of effects on soil microbial communities have taken place in environments contaminated with multiple metals, and some have attempted to separate the effects of individual metals when possible. Soil microbial activity was generally diminished, but in some cases recovered over time. Species and genotype composition were consistently altered, and those changes were long-lasting or permanent. Recent studies have addressed differences in sensitivity between species explicitly, and have clearly demonstrated high variability between related species, as well as within larger taxonomic groupings. Mammalian no observed effect concentration (NOEC) values expressed as blood Pb levels were shown to vary by a factor of 8, while avian blood NOECs varied by a factor of 50 (Buekers et al., 2009). Protective effects of dietary Ca^{2+} have been found in plants, birds, and invertebrates.

2.7.2 Summary of Effects on Aquatic Ecosystems

Effects of Pb on plants, invertebrates, and vertebrates are reported for both freshwater and saltwater ecosystems. Although effects of Pb exposure are likely mediated through common mode(s) of action across freshwater and marine/estuarine taxa, these ecosystems are considered separately because of different environmental and physiological factors that influence Pb toxicity such as bioavailability of the metal, form of Pb, water quality parameters and adaptations in freshwater and saltwater organisms. Toxicity of Pb also varies by organism, lifestage and duration of exposure. (U.S. EPA, 2006b, 1986a). Closely related organisms can vary greatly in bioaccumulation of Pb and other non-essential metals as well as in their susceptibility to Pb. Pb effects on aquatic biota were previously assessed in the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD (U.S. EPA, 2006b, 1986a, 1977).

Exposure of freshwater and estuarine organisms to Pb, and associated effects are tied to terrestrial systems via watershed processes (Section 7.2). Atmospherically-derived Pb can enter aquatic systems through runoff from terrestrial systems or via direct deposition over a water surface. In aquatic ecosystems affected by Pb, exposures are most likely characterized as low dose, chronic exposures. Once Pb enters surface waters, its fate and bioavailability are influenced by Ca^{2+} concentration, pH, alkalinity, total suspended solids, and dissolved organic carbon (DOC), includinig humic acids. In saltwater, higher levels of ions additionally affect Pb bioavailability. In sediments, Pb bioavailability may be influenced by the presence of other metals, sulfides, iron (Fe-) and manganese (Mn-)oxides, and physical disturbance. Recent studies provide further evidence for the

role of modifying factors such as pH, DOC, and hardness. Toxicity of the same concentration of Pb can vary greatly under different experimental conditions.

As recognized in the 2006 Pb AQCD and further supported in this review, uptake of Pb by aquatic invertebrates and vertebrates may preferentially occur via exposure routes other than direct absorption from the water column such as ingestion of contaminated food and water, uptake from sediment pore waters, or incidental ingestion of sediment (U.S. EPA, 2006b). Currently available models for predicting bioavailability focus on acute toxicity and do not consider all possible routes of uptake. They are therefore of limited applicability, especially when considering species-dependent differences in uptake and bioaccumulation of Pb. Recent evidence supports the 2006 Pb AQCD conclusion that processes such as Pb adsorption, complexation, and chelation alter bioavailability to aquatic organisms.

Biological Effects of Pb on Freshwater Plants, Invertebrates and Vertebrates

Recent evidence further supports the findings of the previous Pb AQCDs that waterborne Pb is highly toxic to freshwater plants, invertebrates and vertebrates, with toxicity varying with species and lifestage, duration of exposure, form of Pb, and water quality characteristics. Concentration-response data from freshwater organisms indicate that there is a gradient of response to increasing Pb concentration and that some effects in sensitive species are observed at concentrations of Pb quantified in U.S. surface waters (Table 2-1).

The toxicity of Pb to aquatic algae and plants has been recognized in earlier EPA reviews of this metal. In the 1977 Pb AQCD, differences in sensitivity to Pb among different species of algae were reported and concentrations of Pb varied within and between genera. This observation was subsequently generalized across aquatic taxa (U.S. EPA, 1977). At the time of the 1977 Pb AQCD, the information available on effects of Pb on freshwater plants was limited. For plants in general, Pb was recognized to affect photosynthesis, mitosis, and growth, but at concentrations higher than typically found in the environment. Effects of Pb on plants reported in subsequent Pb AQCDs included decreased growth, deformation of cells, and blocking of the pathways that lead to pigment synthesis, thus affecting photosynthesis.

Effects of Pb on aquatic plants supported by additional evidence in this review include oxidative damage, decreased photosynthesis, and reduced growth. Most recent studies report effects on growth at concentrations much higher than Pb typically encountered in the environment, however, some sublethal endpoints such as effects on chlorophyll were reported at lower concentrations, albeit still much higher than those typically encountered

in U.S. surface waters (in the 100 to 200 µg Pb/L range). Elevated levels of antioxidant enzymes are commonly observed in aquatic plant, algae, and moss species exposed to Pb (U.S. EPA, 1977) and recent evidence continues to support this observation. Recent studies on uptake of Pb by aquatic plants support the findings of previous Pb AQCDs that all such plants with roots tend to sequester larger amounts of Pb in their roots than in their shoots, and provide additional evidence for species differences in compartmentalization of sequestered Pb and in responses to Pb in water and sediments. Exposure-response relationships in which increasing concentrations of Pb leads to increasing effects have consistently been reported in freshwater algae and macrophytes, suggesting that effects on growth and antioxidant activity are also occurring at lower concentrations, however, most current observations of Pb effects in freshwater plants are at concentrations that exceed Pb concentration values available for U.S. surface waters (Table 2-1).

The largest body of evidence for effects of Pb at or near concentrations encountered in U.S. surface waters is from invertebrates. In the 1986 Pb AQCD (U.S. EPA, 1986a) and 2006 Pb AQCD (U.S. EPA, 2006b), reduced reproduction, growth, and survival were reported in various species of freshwater invertebrates. In the 2006 Pb AQCD, concentrations at which effects were observed in aquatic invertebrates ranged from 5 to 8,000 µg Pb/L. Recent evidence for effects of Pb on reproduction, growth, and survival supports findings in previous Pb AQCDs. In a series of 48-hour acute toxicity tests using a variety of natural waters across North America, LC_{50} values ranged from 29 to 180 µg Pb/L tests with the cladoceran *Ceriodaphnia dubia* (Esbaugh et al., 2011). In this same species, increased DOC leads to an increased mean EC_{50} for reproduction as low as 25 µg Pb/L. Reproductive and growth effects have also been reported in rotifer, midge and mayfly species near the range of Pb concentrations encountered in freshwater habitats. Several studies in this review have provided evidence of growth effects at lower concentrations. Among the most sensitive species, growth of juvenile freshwater snails (*Lymnaea stagnalis*) was inhibited at an EC_{20} of <4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006b). A chronic value of 10 µg Pb/L, obtained in 28-day exposures of 2-month-old freshwater mussel (*Lampsilis siliquoidea*) juveniles, was the lowest genus-mean chronic value ever reported for Pb (Wang et al., 2010e).

Since the 2006 Pb AQCD, there is additional evidence for Pb effects on antioxidant enzymes, lipid peroxidation, stress response and osmoregulation in aquatic invertebrates, as well as additional information on Pb bioaccumulation. Recent studies using stable isotopes have enabled simultaneous measurement of uptake and elimination in several aquatic organisms to assess the relative importance of water versus dietary uptake. In uptake studies of various invertebrates, Pb was mainly found in the gills and digestive gland/hepatopancreas.

Pb effects on freshwater vertebrates were previously assessed in the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD (U.S. EPA, 2006b, 1986a, 1977). Evidence of toxicity of Pb and other metals to freshwater organisms goes back to early observations of contamination of natural areas by Pb mining leading to extirpation of fish from streams (U.S. EPA, 1977). Recent evidence supports the findings of effects on survival, reproduction, and behavior reported in previous Pb AQCDs for freshwater vertebrates. In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L (Esbaugh et al., 2011). Reproductive effects associated with water quality parameters were also noted with this species (Mager et al., 2010). In fish, several recent studies on behavioral effects of Pb indicate decreased prey capture rate, slower swim speed and decline in startle response and visual contrast with Pb exposure. These reported effects provide additional evidence for toxicity of Pb to fish. Chronic NOEC and EC_{10} values reported for trout, a sensitive species, are within the range of Pb occasionally encountered in U.S. surface waters (Table 7-2).

Observed responses of fish to Pb reported in the 1986 Pb AQCD and the 2006 Pb AQCD included inhibition of heme formation, alterations in brain receptors, effects on blood chemistry and hormonal systems, and decreases in some enzyme activities (U.S. EPA, 2006b, 1986a). Since the 2006 Pb AQCD, possible molecular targets for Pb neurotoxicity have been identified in fish and additional mechanisms of Pb toxicity have been elucidated in the fish gill and the fish renal system. In the 2006 Pb AQCD, amphibians were considered to be relatively tolerant to Pb. Observed responses to Pb exposure included decreased enzyme activity (e.g., ALAD reduction) and changes in behavior. Since the 2006 Pb AQCD, studies conducted at concentrations approaching environmental levels of Pb have indicated sublethal effects on tadpoles including deformities and decrements in growth and swimming ability.

In the 2006 Pb AQCD, adverse effects were found in freshwater fish at concentrations ranging from 10 to >5,400 µg Pb/L, generally depending on water quality variables (e.g., pH, hardness, salinity). Additional testing of Pb toxicity under conditions of varied alkalinity, DOC, and pH has been conducted since the last review. Effects in fish observed in recent studies fall within the range of concentrations observed in the previous Pb AQCD. Recent evidence also supports the 2006 conclusions that the gill is a major site of Pb uptake in fish, and that there are species differences in the rate of Pb accumulation and distribution of Pb within the organism. The anterior intestine has been newly identified as a site of uptake of Pb through dietary exposure studies. At the time of the publication of the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be negligible. Measured concentrations of Pb in the tissues of aquatic organisms were generally higher in algae and benthic organisms than in consumers at

higher trophic levels, indicating that Pb was bioconcentrated but not biomagnified. Some studies published since the 2006 Pb AQCD support the potential for transfer of Pb in aquatic food webs, while other studies indicate that Pb concentration decreases with increasing trophic level.

Ecosystem-level effects associated with Pb reported in previous Pb AQCDs include alteration of predator-prey dynamics, species richness, species composition, and biodiversity. Since the 2006 Pb AQCD, additional evidence for community and ecosystem level effects of Pb have been observed primarily in microcosm studies or field studies near contaminated areas (mining, effluent). Findings from field studies of aquatic communities in the vicinity of heavily contaminated sites include changes in species composition and species richness, predator/prey interactions, nutrient cycling and energy flow; however, Pb is often found coexisting with other metals and other stressors, which risk confounding the observed effects. Recent studies provide evidence in additional habitats for these community and ecological-level effects, specifically in aquatic macrophyte communities and sediment-associated communities. Different species may exhibit different responses to Pb-impacted ecosystems dependent not only upon other environmental factors (e.g., temperature, pH), but also on species sensitivity, lifestage, or seasonally-affected physiological state. Aquatic ecosystems with low pH and low dissolved organic matter are likely to be the most sensitive to the effects of atmospherically-deposited Pb.

Biological Effects of Pb on Saltwater Plants, Invertebrates and Vertebrates

In general, Pb toxicity to marine/estuarine plants, invertebrates and vertebrates is less well characterized than toxicity to Pb in freshwater systems due to an insufficient quantity of studies on saltwater organisms. In marine algae, effects on growth are observed in the most sensitive species at Pb concentrations that exceed amounts measured in the open sea or estuaries (Table 2-1). The majority of available studies of Pb effects on saltwater organisms are for invertebrate species. Evidence for Pb effects on reproduction, growth and survival as well as neurobehavioral, hematological and physiological stress endpoints are coherent with findings in freshwater invertebrates although most effects are observed at concentrations above 100 µg Pb/L which exceeds Pb typically encountered in seawater (Table 2-1). Fewer studies are available for Pb in marine sediments. In the amphipod, *Elasmopus laevis*, onset to reproduction was significantly delayed at 118 mg/Pb kg sediment; a concentration that the authors indicate is below the current marine sediment regulatory guideline for Pb (218 mg Pb/kg sediment) (Ringenary et al., 2007; NOAA, 1999). In the same study, no effects of Pb on adult survival in 28-day or 60-day sediment exposures were observed. Additional studies on reproduction, growth, and survival in marine invertebrates report effects above the

range considered for causal determinations (Table II Preamble). Several field monitoring studies with marine bivalves have used ALAD as a biomarker for Pb exposure and correlated ALAD inhibition to increased Pb tissue content. Field and laboratory studies provide evidence for antioxidant response to Pb exposure, however, most effects are observed at concentrations of Pb that are higher than concentrations detected in marine environments. No recent evidence for effects of Pb on marine vertebrates in controlled exposures was available for review.

2.7.3 Determinations of Causality for Effects on Ecosystems

Table 2-3 Summary of Pb causal determinations for plants, invertebrates and vertebrates.

Level		Effect	Terrestrial[a]	Freshwater[a]	Saltwater[a]
Community- and Ecosystem-Level		Community and Ecosystem Effects (Sections 7.3.12.7, 7.4.12.7, and 7.4.21.7)	Likely Causal	Likely Causal	Inadequate
Population–Level Endpoints	**Organism–Level Responses**	Reproductive and Developmental Effects - Plants (Sections 7.3.12.1, 7.4.12.1, and 7.4.21.1)	Inadequate	Inadequate	Inadequate
		Reproductive and Developmental Effects - Invertebrates (Sections 7.3.12.1, 7.4.12.1, and 7.4.21.1)	Causal	Causal	Suggestive
		Reproductive and Developmental Effects - Vertebrates (Sections 7.3.12.1, 7.4.12.1, and 7.4.21.1)	Causal	Causal	Inadequate
		Growth - Plants (Sections 7.3.12.2, 7.4.12.2, and 7.4.21.2)	Causal	Likely Causal	Inadequate
		Growth - Invertebrates (Sections 7.3.12.2, 7.4.12.2, and 7.4.21.2)	Likely Causal	Causal	Inadequate
		Growth - Vertebrates (Sections 7.3.12.2, 7.4.12.2, and 7.4.21.2)	Inadequate	Inadequate	Inadequate
		Survival - Plants (Sections 7.3.12.3, 7.4.12.3, and 7.4.21.3)	Inadequate	Inadequate	Inadequate
		Survival - Invertebrates (Sections 7.3.12.3, 7.4.12.3, and 7.4.21.3)	Causal	Causal	Inadequate
		Survival - Vertebrates (Sections 7.3.12.3, 7.4.12.3, and 7.4.21.3)	Likely Causal	Causal	Inadequate
		Neurobehavioral Effects - Invertebrates (Sections 7.3.12.4, 7.4.12.4, and 7.4.21.4)	Likely Causal	Likely Causal	Inadequate
		Neurobehavioral Effects - Vertebrates (Sections 7.3.12.4, 7.4.12.4, and 7.4.21.4)	Likely Causal	Likely Causal	Inadequate
	Sub-organismal Responses	Hematological Effects - Invertebrates (Sections 7.3.12.5, 7.4.12.5, and 7.4.21.5)	Inadequate	Likely Causal	Suggestive
		Hematological Effects - Vertebrates (Sections 7.3.12.5, 7.4.12.5, and 7.4.21.5)	Causal	Causal	Inadequate
		Physiological Stress - Plants (Sections 7.3.12.6, 7.4.12.6, and 7.4.21.6)	Causal	Likely Causal	Inadequate
		Physiological Stress - Invertebrates (Sections 7.3.12.6, 7.4.12.6, and 7.4.21.6)	Likely Causal	Likely Causal	Suggestive
		Physiological Stress - Vertebrates (Sections 7.3.12.6, 7.4.12.6, and 7.4.21.6)	Likely Causal	Likely Causal	Inadequate

[a]Based on the weight of evidence for causal determination in Table II of the ISA Preamble. Ecological causal determinations are based on doses or exposures generally within one to two orders of magnitude of the range of Pb currently measured in the environment (Table 2-1).

2.7.3.1 Effects on Development and Reproduction

Evidence from invertebrate and vertebrate studies from Pb AQCDs and in this review indicates that Pb is affecting reproductive performance in multiple species. Various endpoints have been measured in multiple taxa of terrestrial and aquatic organisms to assess the effect of Pb on development, fecundity, and hormone homeostasis, and they have demonstrated the presence of adverse effects. Reproductive effects are important when considering effects of Pb because impaired fecundity at the organism level of biological organization can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in terrestrial (Section 7.3.12.1) and freshwater (Section 7.4.12.1) invertebrates and vertebrates. Although there is less evidence for reproductive and developmental effects of Pb in marine systems, available evidence is suggestive of a causal relationship between Pb exposure and reproductive and developmental effects in saltwater invertebrates (Section 7.4.21.1). The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in saltwater vertebrates and in either terrestrial or aquatic plants.

Recent evidence for developmental and reproductive endpoints in terrestrial invertebrates shown to be affected by Pb include hatching success in collembolans, increased development time in fruit flies and aphids, and disrupted hormone homeostasis in moths. These studies have generally used Pb concentrations that exceed Pb soil concentrations found at most U.S. locations (Table 2-1), but many of them included multiple concentrations, and responses increased with increasing concentration. In terrestrial vertebrates, recent evidence for decreased sperm count and quality in deer at a location contaminated by mining, and for decreased testis weight in lizards, support previous associations between Pb exposure and reproductive and developmental effects. Few studies are available that specifically address reproductive effects of Pb exposure in either terrestrial or aquatic plants.

In terrestrial invertebrates, Pb can alter developmental timing, hatching success, sperm morphology, and hormone homeostasis. In fruit flies, Pb exposure increased time to pupation and decreased pre-adult development. Sperm morphology was altered in earthworms exposed to Pb-contaminated soils. Pb may also disrupt hormonal homeostasis in invertebrates as studies with moths have suggested. Evidence of multi-generational toxicity of Pb is also present in terrestrial invertebrates, specifically springtails, mosquitoes, carabid beetles, and nematodes where decreased fecundity in

progeny of Pb-exposed individuals was observed. However, effects have only been studied in a small number of species.

For freshwater invertebrates, exposure to Pb under controlled conditions has provided evidence for reproductive effects on sensitive taxa (gastropods, amphipods, cladocerans) at or near the range of Pb concentration values available for U.S. surface waters (Table 2-1). Reproductive effects were reported to begin at 19 µg Pb/L for the snail *Lymnaea palustris* and 27 µg Pb/L for Daphnia sp. as reported in the 1986 Pb AQCD (U.S. EPA, 1986b). In a 42-day chronic study reviewed in the 2006 Pb AQCD, the LOEC for reproduction was 3.5 µg Pb/L in amphipods receiving both waterborne and dietary Pb (Besser et al., 2005). Several recent studies of snails, clams, and rotifers support previous findings of adverse impacts to embryonic development. Reproductive effects have also been observed in multi-generational studies with aquatic invertebrates. Larval settlement rate and rate of population increase was decreased in rotifers and marine amphipods. Rotifers have a reduced fertilization rate associated with Pb exposure that appears to be due to decreased viability of sperm and eggs.

In freshwater vertebrates there is evidence for reproductive and developmental effects of Pb. Recent evidence in frogs and freshwater fish continues to support developmental and reproductive effects of Pb in aquatic vertebrates reported in earlier Pb AQCDs. Pb-exposure in tadpoles has been demonstrated to delay metamorphosis, decrease larval size, produce subtle skeletal malformations, and to result in slower swimming speed. Previous Pb AQCDs have reported developmental effects in fish, specifically spinal deformities in larvae at a concentration of 120 µg Pb/L. In the 2006 Pb AQCD, decreased spermatocyte development in rainbow trout was observed at 10 µg Pb/L and in fathead minnow testicular damage occurred at 500 µg Pb/L. In more recent studies, reproduction in fathead minnows was affected in breeding exposures following 300-day chronic toxicity testing. However, reproductive performance was unaffected in zebrafish *Danio rerio* exposed to Pb-contaminated prey. In fish, there is recent evidence of Pb effects on steroid profiles from nominal exposure studies.

In terrestrial vertebrates, evidence from Pb AQCDs and more recent evidence support an association between Pb exposure and observed adverse reproductive effects. In mammals, few studies in the field have addressed Pb specifically: most available data in wild or grazing animals are from near smelters, where animals are co-exposed to other metals. Evidence obtained using mammals in the context of human health research demonstrates adverse effects of Pb on sperm, and on onset of puberty in males and females (Chapter 5), which is coherent with the partial evidence from mammals in the wild. Other reproductive endpoints including spontaneous abortions, pre-term birth, embryo development, placental development, low birth weight, subfecundity, hormonal changes,

and teratology were also affected, but less consistently. Recent toxicological data from animal studies support trans-generational effects, a finding that is also an area of emerging interest in ecology.

Many studies of effects on reproductive and developmental endpoints in terrestrial invertebrates and vertebrates have been conducted with soil Pb concentrations exceeding those found in most U.S. locations. Recent and past studies that include multiple, increasing concentrations of Pb, from background level to levels greater than those associated with heavily contaminated sites, showed exposure-dependent responses. For some aquatic species, recent evidence supports previous findings of reproductive and developmental effects of Pb and differential lifestage response at or near concentrations of Pb reported from natural environments.

2.7.3.2 Effects on Growth

Alterations in the growth of an organism can impact population, community and ecosystem level variables. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and effects on growth in terrestrial plants (Section 7.3.12.2) and freshwater invertebrates (Section 7.4.12.2). Evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and effects on growth in terrestrial invertebrates and freshwater plants. Evidence is inadequate to establish a causal relationship between Pb exposures and effects on growth in terrestrial and aquatic vertebrates and saltwater biota (Section 7.4.21.2).

Evidence for effects of Pb on growth is strongest in terrestrial plants. In invertebrates, evidence for effects of Pb on growth has been observed most extensively in freshwater taxa, with inhibition in sensitive species occurring in or near the range of Pb concentration values found in surveys of U.S. surface waters (Table 2-1). Vertebrates, particularly terrestrial, have been the object of a comparatively much smaller number of studies of the effects of Pb on growth. Growth effects observed in both invertebrates and vertebrates, however, underscore the importance of lifestage to overall Pb susceptibility. In general, juvenile organisms are more sensitive than adults. Evidence for growth effects of Pb in freshwater and terrestrial plant species is primarily supported by earlier Pb AQCDs. In aquatic invertebrates, the weight of the evidence continues to support growth effects of Pb with several recent studies reporting effects at ≤ 10 µg Pb/L, specifically in snails and mussels. Also, growth effects in frogs are reported at lower concentrations in the current document than in earlier reviews.

There is evidence over several decades of research that Pb inhibits photosynthesis and respiration in plants, both of which reduce growth (U.S. EPA, 2006b, 1977). Many

toxicity studies conducted in laboratory and greenhouse settings have reported effects on plants. These effects are typically observed in laboratory studies with high exposure concentrations or in field studies near stationary sources and heavily contaminated sites, but studies that include multiple concentrations of Pb show increased response with increasing concentration. Pb has been shown to affect photosystem II, altering the pigment structure, and decreasing the efficiency of visible light absorption by affected plants. Decreases in chlorophyll *a* and *b* content have been observed in various algal and plant species. Most primary producers experience EC_{50} values for growth in the range of 1,000 to 100,000 µg Pb/L with minimal inhibition of growth observed as low as 100 µg Pb/L (U.S. EPA, 2006b).

Growth effects of Pb on aquatic invertebrates are reviewed in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and the 2006 Pb AQCD (U.S. EPA, 2006b). In the 2006 Pb AQCD, the LOEC for growth of freshwater amphipods *Hyalella azteca* in 42-day chronic exposure to Pb was 16 µg Pb/L (Besser et al., 2005). Recent studies provide additional evidence for effects on growth of aquatic invertebrates at ≤ 10 µg Pb/L. Growth of juvenile freshwater snails *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} <4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006b). In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. The authors indicated that the observed effect level for Pb was very close to the current U.S. EPA water quality criteria for Pb (3.3 µg Pb/L normalized to test water hardness) (Grosell and Brix, 2009). In the freshwater mussel, fatmucket (*L. siliquoidea*) juveniles were the most sensitive lifestage (Wang et al., 2010e). A chronic value of 10 µg Pb/L in a 28-day exposure of 2-month-old fatmucket juveniles was the lowest genus mean chronic value ever reported for Pb. Growth effects are also reported in marine invertebrates at higher concentrations of Pb than sensitive freshwater invertebrates.

In Pb AQCDs, a few studies have reported growth effects of Pb on vertebrates including fish (growth inhibition), birds (changes in juvenile weight gain), and frogs (delayed metamorphosis, smaller larvae). A recent study reviewed in this ISA supports findings of growth effects in frogs and suggests that these effects may be occurring at lower concentrations than previously reported: the growth rate of tadpoles of the northern leopard frog exposed nominally to 100 µg Pb/L from embryo to metamorphosis was slower than the growth rate of the controls (Chen et al., 2006b). In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations reported in wild-caught populations. Reports of Pb-associated growth effects in fish are inconsistent.

2.7.3.3 Effects on Survival

Survival is a biologically important response that may have a direct impact on population size and can lead to effects at the community and ecosystem level of biological organization. The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and survival in terrestrial invertebrates (Section 7.3.12.3) and freshwater invertebrates and vertebrates (Section 7.4.12.3). Evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and survival in terrestrial vertebrates (Section 7.3.12.3). The evidence is inadequate to conclude that there is a causal relationship between Pb exposure and survival in terrestrial and freshwater plants (Section 7.3.12.3, and Section 7.4.12.3), as well as in all saltwater biota (Section 7.4.21.3). There is evidence for mortality in saltwater organisms at concentrations that greatly exceed Pb concentrations typically encountered in seawater. In general, marine organisms are less sensitive to Pb than freshwater species.

In terrestrial vertebrates, evidence for Pb effects on survival is primarily supported by Pb AQCDs with no recent studies reporting effects on survival at lower concentrations. For aquatic invertebrates recent studies support previous associations between Pb exposure and mortality at concentrations near the range of Pb concentration values available for U.S. surface waters (Table 2-1) in cladocerans, amphipods, and rotifers. In aquatic vertebrates, there is recent evidence for effects in fish at <100 µg Pb/L. Pb is generally not phytotoxic to freshwater or terrestrial plants at concentrations found in the environment away from stationary sources and heavily contaminated sites, probably due to the fact that plants often sequester large amounts of Pb in roots, and that translocation to other parts of the plant is limited.

The relationship between Pb exposure and decreased survival rate has been well demonstrated in terrestrial and aquatic species, as presented in Sections 7.3.12.3, 7.4.12.3, 7.4.21.3, and in previous Pb AQCDs. Toxicological studies have established LC_{50} values for some species of plants, invertebrates, and vertebrates. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa. LC_{50} values are usually much higher than Pb concentrations near contaminated sites, although physiological dysfunction that adversely impacts the fitness of an organism often occurs well below concentrations that result in mortality.

Freshwater aquatic invertebrates are generally more sensitive to Pb exposure than other taxa, with survival adversely impacted in a few species at concentrations near typical ambient levels. Freshwater biota that exhibit sensitivity to Pb in the upper range of Pb concentrations measured in U.S. waters [median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L (U.S. EPA, 2006b)], include some species of gastropods, amphipods, cladocerans, and rotifers although the toxicity of Pb is highly dependent upon water quality variables such

as DOC, hardness, and pH. For example, amphipods tested under various water conditions exhibited sensitivity to Pb at <10 µg Pb/L (U.S. EPA, 2006c) and the present document). These impacted species may include endangered species or candidates for the endangered species list, such as the freshwater mussel *Lampsilis rafinesqueana* (Neosho mucket). The EC_{50} for foot movement (a measure of viability) for newly transformed juveniles of this species was 188 µg Pb/L. Other aquatic invertebrates such as odonates may be tolerant of Pb concentrations that greatly exceed Pb detected in aquatic ecosystems.

Terrestrial invertebrates typically tolerate high concentrations of Pb relative to concentrations found in most uncontaminated soils. In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 µg Pb/g dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. LC_{50} values for soil nematodes vary from 10-1,550 mg Pb/kg dry weight dependent upon soil organic matter content and soil pH (U.S. EPA, 2006b). In earthworms, 14 and 28 day LC_{50} values typically fall in the range of 2,400-5,800 mg Pb/kg depending upon the species tested.

Data on mortality of saltwater species associated with exposure to Pb is limited; however, in general, marine organisms are less sensitive to this metal than freshwater organisms and the highest toxicity is observed in juveniles. In one study, effects of Pb on survival at environmentally relevant concentrations of Pb in diet have been demonstrated through a simulated marine food chain in which the primary producer, the microalgae *Tetraselmis suecica*, was exposed nominally to 20 µg Pb/L and subsequently fed to brine shrimp *Artemia franciscana*, (mean Pb content 12 to 15 µg Pb/g) which were consumed by white-leg shrimp *Litopenaeus vannamei*, itself consumed by grunt fish *Haemulon scudderi* representing the top of the marine food chain (Soto-Jiménez et al., 2011b). Survival of brine shrimp was 25 to 35% lower than the control and both white shrimp and grunt fish had significantly higher mortalities than controls.

In vertebrates, toxicity is observed in terrestrial avian and mammalian species in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight-day) as reviewed for the guidance and development of ecological soil screening levels (Eco-SSLs) (U.S. EPA, 2005b). The NOAELs for survival ranged from 3.5 to 3,200 mg Pb/kg • day. In freshwater vertebrates there is considerable historic information on Pb toxicity to fish. Recent studies support earlier AQCD findings of Pb effects on fish survival and indicate effects at lower concentrations when testing with juvenile lifestages. In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011). Thirty day

LC_{50} values for larval fathead minnows ranged from 39 to 1,903 µg Pb/L in varying concentrations of DOC, calcium sulfate ($CaSO_4$), and at various pH values (Grosell et al., 2006b). In a recent study of rainbow trout fry at 2-4 weeks post-swim up, the 96-hour LC_{50} was 120 µg Pb/L at a hardness of 29 mg/L as calcium carbonate ($CaCO_3$), a value much lower than in testing with older fish (Mebane et al., 2008). In the same study, two chronic (>60 day) tests were conducted with rainbow trout and the NOECs for survival were 24 and 87 µg Pb/L and the LOECs were 54 and 125 µg Pb/L, respectively.

2.7.3.4 Neurobehavioral Effects

Overall, the evidence from terrestrial and freshwater systems is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and neurobehavioral effects in invertebrates and vertebrates (Sections 7.3.12.4 and 7.4.12.4). Evidence is inadequate to conclude that there is a causal relationship between Pb exposure and neurobehavioral endpoints in saltwater species (Section 7.4.21.4).

Observations from laboratory studies reported in Chapter 7 and previous Pb AQCDs have shown adverse effects of Pb on neurological endpoints in both terrestrial and freshwater animal taxa. Studies that consider mode-of-action and molecular targets of Pb toxicity in biota are now available for a few species. Recent studies have continued adding to the evidence from both invertebrate and vertebrate studies that Pb adversely affects behaviors such as food consumption, avoidance, and escape from predators, behavioral thermoregulation, and prey capture. These changes are likely to decrease the overall fitness of the organism. Recent evidence includes reports of behavioral responses across a larger variety of organisms including fish larvae born from Pb-exposed adults and reptiles, while some impairments in feeding and escaping behaviors were reported for the first time.

Central nervous system effects in fish recognized in previous Pb AQCDs include effects on spinal neurons and brain receptors. Recent evidence from this review identifies possible molecular targets for Pb neurotoxicity in fish. Additionally, there is recent evidence for neurotoxic action of Pb in invertebrates with exposure to Pb observed to cause changes in the morphology of gamma aminobutyric acid (GABA)-motor neurons in nematodes (*Caenorhabditis elegans*) (Du and Wang, 2009).

Decreased food consumption of Pb-contaminated diet has been demonstrated in some invertebrates (snails) and vertebrates (lizards, pigs, fish). Behavioral effects in grunt fish *H. scudderi*, occupying the top level of a simulated marine food chain included lethargy and decreased food intake in a 42-day feeding study (Soto-Jiménez et al., 2011b). These fish were fed white shrimp exposed to Pb via brine shrimp that were initially fed

microalgae cultured nominally at 20 µg Pb/L. In the same study, surfacing, reduction of motility, and erratic swimming were observed in the white shrimp after 30 days of exposure to Pb via diet. Pb may also decrease the ability of an organism to capture prey or escape predation. For example, Pb exposure has been demonstrated to adversely affect prey capture ability of certain fungal and fish species, and the motility of nematodes was adversely affected in Pb-contaminated soils (Wang and Xing, 2008). Prey capture ability was decreased in 10-day-old fathead minnows born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a 21-day breeding assay (Mager et al., 2010). Altered pattern of escape swimming in larval zebrafish exposed to Pb as embryos was reported at low nominal concentrations of Pb (2 and 6 µg Pb/L). Other behavioral effects of Pb observed in fish include increased hyperactivity and decreased ability to detect visual contrast. In a laboratory study, Pb-exposed gull chicks exhibited abnormal behaviors such as decreased walking, erratic behavioral thermoregulation and food begging that could make them more vulnerable in the wild (Burger and Gochfeld, 2005). The chicks were exposed to Pb via injection to produce feather Pb concentration approximately equivalent to those observed in wild gulls. Lizards exposed to Pb through diet in the laboratory exhibited abnormal coloration and posturing behaviors. These findings show strong coherence with findings from studies in laboratory animals that show that Pb induces changes in learning and memory (Section 5.3.2.3), as well as attention (Section 5.3.3) and motor function (Section 5.3.8).

2.7.3.5 Hematological Effects

Based on observations in both terrestrial and freshwater organisms and additionally supported by toxicological and epidemiological findings in laboratory animals and humans, evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial and aquatic vertebrates (Sections 7.3.12.5 and 7.4.12.5). The evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and hematological effects in freshwater invertebrates and inadequate to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial invertebrates. Limited evidence from marine invertebrates is suggestive of a causal relationship between Pb exposures and hematological effects (Section 7.4.21.5). The mode of action of Pb on ALAD activity is likely mediated through a common pathway in terrestrial, freshwater and saltwater organisms.

Recent studies add support to the strong body of evidence presented in Pb AQCDs that Pb exposure is associated with hematological responses in terrestrial and aquatic vertebrates. Lower ALAD activity has been significantly correlated with elevated blood

Pb levels in fish and mammals. In the 1986 Pb AQCD, decreases in RBC ALAD activity following Pb exposure were well documented in birds and mammals (U.S. EPA, 1986a). The draft Ambient Aquatic Life Water Quality Criteria for Pb summarized several studies of ALAD activity in fish (U.S. EPA, 2008b). Further evidence from the 2006 Pb AQCD and this review suggests that this enzyme is an indicator for Pb exposure across a wide range of taxa. Since the 2006 Pb AQCD, evidence of Pb effects on ALAD activity has been found in additional species of invertebrates and fish, and has been identified in bacteria. ALAD activity has been shown to vary greatly between species. In addition to consideration of ALAD activity, there is recent evidence for deceased white blood cell counts in amphibians affected by Pb exposure. The consistency and coherence of these findings of effects on ALAD activity in vertebrates are also supported by some evidence of Pb-induced alterations of blood chemistry in fish reported in the 2006 Pb AQCD (U.S. EPA, 2006b). This evidence is strongly coherent with observations from human epidemiologic and animal toxicology studies where a causal relationship was identified between Pb exposure and decreased RBC survival and function, and altered heme synthesis in humans and laboratory animals (Sections 2.6.5 and 5.7).

In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure in invertebrates as well as vertebrates (U.S. EPA, 2006b). Recent field studies of ALAD activity include observations in songbirds and owls near historical mining areas and in bivalves collected from freshwater and estuarine environments. Evidence for hematological effects of Pb in saltwater invertebrates is limited primarily to field monitoring studies with bivalves.

2.7.3.6 Effects on Physiological Stress

Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in terrestrial plants (Section 7.3.12.6). Evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and physiological stress in terrestrial invertebrates and vertebrates (Section 7.3.12.6) as well as freshwater plants, invertebrates and vertebrates (Section 7.4.12.6). Further evidence in saltwater invertebrates is suggestive of a causal relationship between Pb exposures and physiological stress (Section 7.4.21.6). Evidence is inadequate to conclude that there is a causal relationship between Pb exposure and physiological stress responses in saltwater plants and vertebrates.

Endpoints associated with physiological stress received no consideration prior to the 2006 Pb AQCD. Studies reviewed in the 2006 Pb AQCD reported stress-related effects including upregulation of antioxidant enzymes and increased lipid peroxidation (U.S.

EPA, 2006b). Recent evidence in additional species of terrestrial and freshwater plants, invertebrates and vertebrates support, and expand upon findings in the previous Pb AQCD. Some of these studies report findings within one to two orders of magnitude of the range of Pb concentrations measured in terrestrial and freshwater environments (Table 2-1). Recent studies include evidence for production of reactive oxygen species in terrestrial plant species and in freshwater algae and fish in response to Pb exposure.

In the current document and the 2006 Pb AQCD (U.S. EPA, 2006b), there is strong evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure in many species of plants, invertebrates and vertebrates. In plants, increases of antioxidant enzymes with Pb exposure occur in algae, aquatic mosses, floating and rooted aquatic macrophytes, and terrestrial species. Most observations of antioxidant responses in plants typically occur at concentrations of Pb higher than found in the environment. However, in a few terrestrial plant species, increases of antioxidant enzymes occur at concentrations approaching the average Pb concentrations in U.S. soils (Table 2-1) and limited transplantation studies with aquatic plants indicate elevated antioxidant enzyme activity associated with Pb levels measured in sediments at polluted sites. There is evidence for antioxidant activity in invertebrates, including gastropods, mussels, and crustaceans, in response to Pb exposure. Some recent evidence for invertebrate antioxidant responses in freshwater bivalves, and marine bivalve and crustacean species indicates effects at Pb concentrations associated with polluted sites. Markers of oxidative damage are also observed in fish, amphibians, and mammals, both in the laboratory and in exposed natural environments. Across all biota, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

Additional stress responses observed in terrestrial and freshwater invertebrates include elevated heat shock proteins, osmotic stress and decreased glycogen levels. Heat shock protein induction by Pb exposure has been observed in zebra mussels and mites. Tissue volume regulation is adversely affected in freshwater crabs and glycogen levels decreased in freshwater snails following Pb exposure. Although correlated with Pb exposure, these responses are non-specific and may be altered with exposure to any number of environmental stressors.

Upregulation of antioxidant enzymes and increased lipid peroxidation are considered to be reliable biomarkers of stress, and suggest that Pb exposure induces a stress response in those organisms, which may increase susceptibility to other stressors and reduce individual fitness. The oxidative stress responses associated with Pb exposure are consistent in terrestrial biota and in freshwater organisms. Furthermore, these responses are also observed in experimental animal studies.

2.7.3.7 Community and Ecosystem Effects

More evidence for Pb toxicity to terrestrial and aquatic biota has been reported from single-species assays in laboratory studies than from whole ecosystem studies. The evidence is strong for effects of Pb on growth, reproduction, and survival in very diverse species, but considerable uncertainties exist in generalizing effects observed under particular, small-scale conditions, up to the ecosystem level of biological organization. At the ecosystem level, the presence of multiple stressors, variability in field conditions, and differences in bioavailability of Pb make it difficult to measure the magnitude of effects, and to quantify relationships between ambient concentrations of Pb and ecosystem response. However, the cumulative evidence that has been reported for Pb effects at higher levels of biological organization and for endpoints in single species with direct relevance to population and ecosystem level effects (i.e., development and reproduction, growth, survival) is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and the alteration of species richness, species composition and biodiversity in terrestrial and freshwater ecosystems (Sections 7.3.12.7 and 7.4.12.7). Evidence is inadequate to conclude that there is a causal relationship between Pb exposure and effects at higher levels of biological organization in saltwater ecosystems (Section 7.4.21.7).

Ecosystem-level studies *in situ* are complicated by the frequent confounding of Pb exposure in Pb-polluted sites with other factors such as other trace metals and acidic deposition. In those natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity. In laboratory studies and simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions, and contaminant avoidance. At higher levels of biological organization, these effects may change species abundance and community structure. Uptake of Pb into aquatic and terrestrial organisms and its effects on survival, growth, and reproductive endpoints at the organism level are expected to have ecosystem-level consequences. Where evidence of effects is observed at the ecosystem level of organization, evidence from lower levels brings consistency and plausibility for causality.

Most direct evidence of community and ecosystem level effects is from near stationary sources and contaminated sites where Pb concentrations are higher than typically observed in the environment. For terrestrial systems, evidence of impacts on natural ecosystems near smelters, mines, and other industrial sources of Pb has been assembled in previous decades. Those impacts include decreases in species diversity and changes in floral and faunal community composition. For freshwater systems, the literature focuses on evaluating ecological stress from Pb originating from urban and mining effluents

rather than atmospheric deposition. Some organisms exhibit contaminant avoidance behaviors when exposed to Pb-contaminated areas. For example, snails and fish avoid higher concentrations of Pb while frogs and toads lack avoidance response. Recent evidence, published since the 2006 Pb AQCD indicates that some species of worms will avoid Pb-contaminated soils (Langdon et al., 2005).These dynamics are likely to change species abundance and community structure at higher levels of biological organization.

Recent studies continue to demonstrate associations between Pb exposures and effects at higher levels of biological organization that were shown in field and microcosm studies in previous Pb AQCDs. Recent studies on plant and soil microbial communities and sediment-associated and aquatic plant communities increase the total number of types of ecological associations impacted by Pb. In terrestrial ecosystems, most studies show decreases in microorganism abundance, diversity, and function with increasing soil Pb concentration. Specifically, shifts in nematode communities, bacterial species, and fungal diversity have been observed. Furthermore, presence of arbuscular mycorrhizal fungi may protect plants growing in Pb-contaminated soils. Increased plant diversity ameliorated effects of Pb contamination on a microbial community.

In aquatic ecosystems, Pb effects reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) included reduced species abundance, richness and diversity, decreased primary productivity, and altered predator-prey interactions. Since the 2006 Pb AQCD, there is further evidence for effects of Pb in sediment-associated communities in both saltwater and freshwater systems. Community structure and nematode diversity were altered in a microcosm study with marine sediments (Mahmoudi et al., 2007). Sediment-bound Pb contamination appears to differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics in small urban streams (Kominkova and Nabelkova, 2005). Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in sediment were high enough to pose a risk to the benthic community (e.g., 34-101 mg Pb/kg). These risks were observed to be linked to benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than benthic predators and collector-filterers.

Changes to aquatic plant community composition have been observed in the presence of elevated surface water Pb concentrations. A shift toward more Pb-tolerant species is also observed in terrestrial plant communities near smelter sites (U.S. EPA, 2006b). Certain types of plants such as rooted and submerged aquatic plants may be more susceptible to aerially-deposited Pb resulting in shifts in Pb community composition. High Pb sediment concentrations are linked to shifts in amphipod communities inhabiting plant structures.

2.8 Integration of Health and Ecological Effects

The health and ecological effects considered for causal determination are summarized in Table 2-4. The health outcomes were nervous system, cardiovascular, renal, immune, effects on heme synthesis and RBC function, reproductive effects, and cancer. The ecological endpoints considered for causal determination were: community and ecosystem level effects, reproductive and developmental effects, growth, survival, neurobehavioral effects, hematological effects, and physiological stress. The evidence relating to specific ecological endpoints is also integrated across aquatic and terrestrial habitats. Further, the substantial overlap between the ecological and health endpoints considered in the causal determinations allowed the integration of the evidence across these disciplines.

Table 2-4 Summary of causal determinations for health and ecological effects.

Outcome/Effect	Human Health Causal Determination[a]	Ecological Receptors Causal Determination[a]
Nervous System Effects[b]	Causal Relationship: Cognition and Attention-Related Behavior Problems in Children	Likely Causal Relationship: Neurobehavioral Effects in Terrestrial and Freshwater Invertebrates and Vertebrates
Cardiovascular Effects	Causal Relationship: Hypertension and Coronary Heart Disease	N/A[e]
Renal Effects	Likely Causal Relationship: Reduced Kidney Function	N/A[e]
Immune System Effects	Likely Causal Relationship: Atopic and Inflammatory Conditions	N/A[e]
Hematologic Effects[c]	Causal Relationship: Heme Synthesis and RBC Function	Causal Relationship: ALAD Activity in Terrestrial and Freshwater Vertebrates Likely Causal Relationship: ALAD activity in Freshwater Invertebrates
Reproductive and Developmental[d]	Causal Relationship: Development and Male Reproductive Function	Causal Relationship: Invertebrates and Vertebrates
Cancer	Likely to be a causal relationship	N/A[e]
Mortality	N/A[e] (The strongest evidence of Pb-induced mortality in humans was observed for cardiovascular disease related mortality and this evidence was considered in determining the causal relationship between Pb exposure and coronary heart disease.)	Causal Relationship: Survival Terrestrial Invertebrates and Freshwater Invertebrates and Vertebrates Likely Causal Relationship: Terrestrial Vertebrates
Growth	N/A[e] (There is evidence from toxicological and epidemiologic studies of Pb effects on postnatal growth, which was considered in determining the causal association between Pb exposure and developmental effects.)	Causal Relationship: Terrestrial Plants and Freshwater Invertebrates Likely Causal Relationship: Freshwater Plants and Terrestrial Invertebrates
Physiological Stress	N/A[e] (In Human Health, oxidative stress was considered as a upstream event in the modes of action of Pb, leading downstream to various effects. Ecological literature commonly uses oxidative stress as a proxy indicator of overall fitness, and thus treats it as an effect.)	Causal Relationship: Terrestrial Plants Likely Causal Relationship: Terrestrial and Freshwater Invertebrates and Vertebrates and Freshwater Plants
Community and Ecosystem Level Effects	N/A[e]	Likely Causal Relationship: Terrestrial and Freshwater Ecosystems

[a]Causal determinations were made within approximately 1-2 orders of magnitude of current levels.

[b]In ecological receptors, the causal determination was developed considering neurobehavioral effects that can be observed in toxicological studies of animal models and studies of ecological effects in vertebrates and invertebrates.

[c]The ecological evidence considered for the causal determination included ALAD activity, blood cell count, and altered serum profiles.

[d]For health effects the strongest evidence was for delayed onset of puberty and effects on sperm. In the ecological literature, a wide range of endpoints, including embryonic development, multigenerational studies, delayed metamorphosis, and altered steroid profiles, was considered.

[e]N/A, not applicable, i.e., Endpoints were not directly comparable the health and ecological evidence.

2.8.1 Modes of Action Relevant to Downstream Health and Ecological Effects

The diverse health and ecological effects of Pb are mediated through multiple, interconnected modes of action. This section summarizes the principal cellular/subcellular effects contributing to modes of action for human health endpoints associated with Pb exposure and the concentrations at which those effects are observed. Then, effects of Pb observed in aquatic and terrestrial species (Section 2.7) are evaluated along with evidence from epidemiological and laboratory animal studies to determine the extent to which common modes of action can be inferred from the observed effects. The rationale for this approach is that the mechanism of Pb toxicity is likely conserved from invertebrates to vertebrates to humans in some organ systems.

Each of the modes of action discussed in Section 5.2 has the potential to contribute to the development of a number of Pb-induced health effects (Table 2-4). Evidence for the majority of these modes of action is observed at low blood Pb levels in humans and laboratory animals, between 2 and 5 µg/dL, and at doses as low as the picomolar range in animals and cells. The concentrations eliciting the modes of action (reported in Table 2-5) are drawn from the available data and do not imply that these modes of action are not acting at lower exposure levels or that these doses represent the threshold of the effect. Also, the data in presented this table does not inform regarding the exposure frequency and duration required to elicit a particular MOA.

Table 2-5 MOAs, their related health effects, and information on concentrations eliciting the MOAs.

Mode of Action [Related Health Effects (ISA Section)]	Concentrations or Doses (Conditions)[a]	
	Blood Pb	**Dose**
Altered Ion Status [All Health Effects of Pb]	3.5 µg/dL (Mean in cord blood; association with cord blood Ca^{2+}ATPase pump activity) Huel et al. (2008)	0.00005 µM free Pb^{2+} (In vitro; 30 minutes; calmodulin activation assay) Kern et al. (2000)
Protein Binding [Renal (5.5), Heme Synthesis and RBC Function (5.7)]	17.0 µg/dL (Concurrent mean in adult workers with wildtype metallothionein expression; increased BP susceptibility) Chen et al. (2010a)	50 µM Pb glutamate (In vitro; 24 hours; increased nuclear protein in neurological cell) Klann and Shelton (1989)
Oxidative Stress [All Heath Effects of Pb (Chapter 5)]	5.4 µg/dL (Concurrent mean in adult male workers; decreased CAT activity in blood) Conterato et al. (In Press)	0.1 µM Pb acetate (In vitro; 48 hours; decreased cellular GSH in neuroblastoma cells) Chetty et al. (2005)
Inflammation [Nervous System (5.3), Cardiovascular (5.4), Renal (5.5), Immune (5.6), Respiratory (5.6.5 and 5.9.6), Hepatic (5.9.1)]	Among males with concurrent blood Pb ≥ 2.5 µg/dL (Increased serum TNF-α and blood WBC count) Kim et al. (2007)	0.01 µM Pb acetate (In vitro; 48 hours; increased cellular PGE_2 in neuroblastoma cells) Chetty et al. (2005)
Endocrine Disruption [Reproductive and Developmental Effects (5.8), Endocrine System (5.9.3) , Bone and Teeth (5.9.4)]	1.7 µg/dL (Lowest blood Pb level at which a relationship could be detected in adult women with both ovaries removed; increased serum follicle stimulating hormone [FSH]) Krieg (2007)	10 µM Pb nitrate (In vitro; 30 minutes; displaced GHRH binding to rat pituitary receptors) Lau et al. (1991)
Cell Death/Genotoxicity [Cancer (5.10), Reproductive and Developmental Effects (5.8), Bone and Teeth (5.9.4)]	3.3 µg/dL (Concurrent median in adult women; increased rate of hypoxanthine guanine phospho ribosyltransferase reporter gene [HPRT] mutation frequency) Van et al. (2004)	0.03 µM Pb acetate (In vitro; 18 hours; increased formation of micronuclei) Bonacker et al. (2005)

[a]This table provides examples of studies that report effects with low doses or concentration; they are not the full body of evidence used to characterize the weight of the evidence. In addition, the levels cited are reflective of the data and methods available and do not imply that these modes of action are not acting at lower Pb exposure or blood Pb levels or that these doses represent the threshold of the effect. Additionally, the blood concentrations and doses (indicating Pb exposure concentrations from in vitro systems) refer to the concentrations and doses at which these modes of action were observed. While the individual modes of action are related back to specific health effects sections (e.g., Nervous System, Cardiovascular), the concentrations and doses given should not be interpreted as levels at which those specific health effects occur.

Ecosystem studies have presented evidence for the occurrence of many of these modes of action in animals, and to some degree in plants, however the connection to ecological outcomes must usually be inferred because ecological studies are typically not designed to address mode of action directly. The level at which Pb elicits a specific effect is more difficult to establish in terrestrial and aquatic systems due to the influence of environmental variables on Pb bioavailability and toxicity and substantial species differences in Pb susceptibility.

The alteration of cellular ion status (including disruption of Ca^{2+} homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) appears to be the major unifying mode of action underlying all subsequent modes of action in plants, animals, and humans (Figure 5-1). Pb can interfere with endogenous cation homeostasis, necessary as a cell signal carrier mediating normal cellular functions. Pb is able to displace metal ions, such as Zn, Mg, and Ca^{2+}, from proteins due to the flexible coordination numbers and multiple ligand binding ability of Pb, leading to abnormal conformational changes to proteins and altered protein function. Disruption of ion transport leading to increased intracellular Ca^{2+} levels is due in part to the alteration of the activity of transport channels and proteins, such as Na^{+}/K^{+} ATPase and voltage-sensitive Ca^{2+} channels. Pb can interfere with these proteins through direct competition between Pb and the native metals present in the protein metal binding domain or through disruption of proteins important in Ca^{2+}-dependent cell signaling, such as protein kinase C (PKC) or calmodulin.

This competition between metals has been reported not only in human systems, but also in fish, snails, and plants. Altered Ca^{2+} channel activity and binding of Pb with Na^{+}/K^{+}ATPase in the gills of fish disrupts the Na^{+} and Cl^{-} homeostasis, which may lead to ionoregulatory failure and death. Ca^{2+} influx and ionoregulation has also been shown to be inhibited by Pb exposure in a sensitive species of snail, leading to a reduction in snail growth. In plants, substitution of the central atom of chlorophyll, Mg, by Pb prevents light-harvesting, resulting in a breakdown of photosynthesis. Pb-exposed animals also have decreased cellular energy production due to perturbation of mitochondrial function.

Disruption of ion transport not only leads to altered Ca^{2+} homeostasis, but can also result in perturbed neurotransmitter function. Evidence for these effects in Pb-exposed experimental animals and cell cultures has been linked to altered neurobehavioral endpoints and other neurotoxicity. Neurobehavioral changes that may decrease the overall fitness of the organism have also been observed in aquatic and terrestrial invertebrate and vertebrate studies. There is evidence in tadpoles and fish to suggest Pb

may alter neurotransmitter concentrations, possibly resulting in some of these neurobehavioral changes.

Altered cellular ion status following Pb exposure can result in the inhibition of heme synthesis. Pb exposure is commonly associated with altered hematological responses in aquatic and terrestrial invertebrates, experimental animals, and human subjects. The proteins affected by Pb are highly conserved across species accounting for the common response seen in human health and ecological studies. This evolutionarily conserved response to Pb is likely the result of the competition of Pb with the necessary metal cofactors in the proteins involved in heme synthesis.

Although Pb will bind to proteins within cells through interactions with side group moieties, thus potentially disrupting cellular function, protein binding of Pb may represent a mechanism by which cells protect themselves against the toxic effects of Pb. Intranuclear and intracytosolic inclusion body formation has been observed in the kidney, liver, lung, and brain following Pb exposure in experimental animals. A number of unique Pb binding proteins have been detected, constituting the observed inclusion bodies. The major Pb binding protein in blood is ALAD with carriers of the ALAD-2 allele potentially exhibiting higher Pb binding affinity. Inhibition of ALAD activity is a widely recognized response to Pb in environments where Pb is present and is considered to be biomarker of Pb exposure in both terrestrial and aquatic biota. Additionally, metallothionein is an important protein in the formation of inclusion bodies and mitigation of the toxic effects of Pb. Protein binding of Pb is a recognized mechanism of Pb detoxification in some terrestrial and aquatic biota. For example, plants can sequester Pb through binding with phytochelatin and some fish have the ability to store accumulated Pb in heat-stable proteins.

A second major mode of action of Pb is the development of oxidative stress, due in many instances to the antagonism of normal metal ion functions. Disturbances of the normal redox state of tissues can cause toxic effects and is involved in the majority of health and ecological outcomes observed after Pb exposure. The origin of oxidative stress produced after Pb exposure is likely a multi-pathway process. Studies in humans and experimental animals provide evidence to conclude that oxidative stress results from oxidation of δ-ALA, NAD(P)H oxidase activation, membrane and lipid peroxidation, and antioxidant enzyme depletion. Evidence of increased lipid peroxidation associated with Pb exposure exists for many species of plants, invertebrates, and vertebrates. Enhanced lipid peroxidation can also result from Pb potentiation of Fe^{2+} initiated lipid peroxidation and alteration of membrane composition after Pb exposure. Increased Pb-induced ROS will also sequester and inactivate biologically active $^{\bullet}NO$, leading to the increased production of the toxic product nitrotyrosine, increased compensatory NOS, and decreased sGC

protein. Pb-induced oxidative stress not only results from increased ROS production but also through the alteration and reduction in activity of the antioxidant defense enzymes. The biological actions of a number of these enzymes are antagonized due to the displacement of the protein functional metal ions by Pb. Increased ROS are often followed by a compensatory and protective upregulation in antioxidant enzymes, such that this observation is indicative of oxidative stress conditions. A number of studies in plants, invertebrates, and vertebrates present evidence of increased antioxidant enzymes with Pb exposure. Additionally, continuous ROS production may overwhelm this defensive process leading to decreased antioxidant activity and further oxidative stress and injury.

In a number of organ systems Pb-induced oxidative stress is accompanied by misregulated inflammation. Pb exposure will modulate inflammatory cell function, production of proinflammatory cytokines and metabolites, inflammatory chemical messengers, and proinflammatory signaling cascades. Cytokine production is skewed toward the production of proinflammatory cytokines like TNF-α and IL-6 as well as leading to the promotion of Th2 response and suppression of Th1cytokines and Th1-related responses.

Pb is a potent endocrine disrupting chemical. Steroid receptors and some endocrine signaling pathways are known to be highly conserved over a broad expanse of animal phylogeny. Pb will disrupt the HPG axis evidenced in humans, other mammals, and fish, by a decrease in serum hormone levels, such as FSH, LH, testosterone, and estradiol. Pb interacts with the hypothalamic-pituitary level hormone control causing a decrease in pituitary hormones, altered growth dynamics, inhibition of LH secretion, and reduction in StAR protein. Pb has also been shown to alter hormone receptor binding likely due to interference of metal cations in secondary messenger systems and receptor ligand binding and through generation of ROS. Pb disrupts hormonal homeostasis in invertebrates necessary for reproduction and development. Pb also may disrupt the HPT axis by alteration of a number of thyroid hormones, possibly due to oxidative stress. These studies have been conducted in humans and animals, including cattle; however the results of these studies are mixed and require further investigation.

Genotoxicity and cell death has been investigated after Pb exposure in humans, animals, plants, and cell models. High level Pb exposure to humans leads to increased DNA damage, however lower blood Pb levels have caused these effects in experimental animals and cells. Reports vary on the effect of Pb on DNA repair activity, however a number of studies report decreased repair processes following Pb exposure. There is some evidence in plants, earthworms, freshwater mussels and fish for DNA damage associated with Pb exposure. There is evidence of mutagenesis and clastogenicity in

highly exposed humans, however weak evidence has been shown in animals and cells based systems. Human occupational studies provide limited evidence for micronucleus formation (>10 µg/dL), supported by Pb-induced effects in both animal and cell studies. Micronucleus formation has also been reported in amphibians. Animal and plant studies have also provided evidence for Pb-induced chromosomal aberrations. The observed increases in clastogenicity may be the result of increased oxidative damage to DNA due to Pb exposure, as co-exposures with antioxidants ameliorate the observed toxicities. Limited evidence of epigenetic effects is available, including DNA methylation, mitogenesis, and gene expression. Altered gene expression may come about through Pb displacing Zn from multiple transcriptional factors, and thus perturbing their normal cellular activities. Consistently positive results have provided evidence of increased apoptosis following Pb exposure.

Overall, Pb-induced health and ecological effects can occur through a number of interconnected and evolutionarily well conserved modes of action that generally originate with the alteration of ion status.

2.9 Policy Relevant Considerations

2.9.1 Public Health Significance

The rationale for establishing the public health significance of the various health endpoints associated with Pb exposure is multifaceted. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that neurodevelopmental effects in children and cardiovascular effects in adults were among the effects best substantiated as occurring at blood Pb levels as low as 5-10 µg/dL (or possibly lower), and that these categories of effects were clearly of the greatest public health concern. The evidence reviewed in the current assessment supports and builds upon this conclusion with recent epidemiologic studies of children reporting deleterious effects in populations with lower mean blood Pb levels than previously reported. The supralinear concentration-response relationship, which is widely documented for Pb and cognitive function in children, does not provide evidence for a threshold for Pb-associated neurodevelopmental effects in the range of blood Pb levels examined (Sections 2.9.3 and 5.3.13)

The World Health Organization (WHO) definition of "health" is "the state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity" (WHO, 1948). By this definition, decrements in health status that are not severe enough to result in the assignment of a clinical diagnosis might reflect a decrement in the well-being of an individual. Further, deficits in subtle indices of health or

well-being may not be observable except in aggregate, at the population level, so the critical distinction between population and individual risk is essential for interpreting the public health significance of study findings. This concept of population risk is relevant to the interpretation of findings regarding both IQ and blood pressure in the assessment of their public health significance.

Weiss et al. (1988) discusses concepts related to understanding the shift in a population distribution of an IQ Score. The conceptual model described by these authors is not based on actual data and assumes that the incremental concentration-response between Pb exposure and IQ is similar in children with high and low intelligence. As shown in Figure 2-1 small shifts in population means are often significant from a public health perspective. Even a small relative risk for a health effect that is highly prevalent in the population can translate into a large increase in the number of clinical cases.

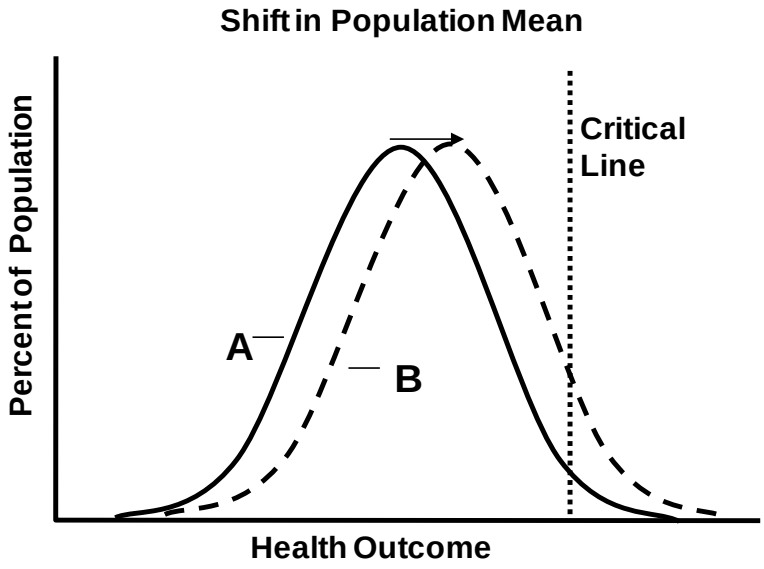

Figure 2-1 The effect of a small shift in population mean on the proportion of individuals in the population diagnosed with clinical disease (i.e., the proportion to the right of the "Critical Line").

For example, small shift in the population mean IQ may result in a substantial increase in the number of individuals functioning in the low range of the IQ distribution, which is associated with increased risk of educational, vocational, and social failure (Section 5.3.13). A downward shift in the mean IQ value can also reduce the proportion of the population achieving very high IQ scores. It is also important to note that the change in a population mean observed in an epidemiologic study may be small compared

to the standard error of measurement for the outcome. Measurement error can affect the likelihood of detecting an association and is not relevant to the size of the association that is detected. If a study is large enough it will have adequate statistical power to detect small changes. Bias may be introduced if the measurement error of the outcome is highly correlated with the exposure. There is no evidence indicating that individuals with higher blood Pb levels test systematically lower than their true IQ.

Pb-associated changes in blood pressure also increase an individual's risk for health effects that are of greater clinical consequence than is suggested by a small individual change in blood pressure. Nawrot et al. (2002) found that a doubling of blood Pb was associated with an approximate 1 mmHg increase in systolic blood pressure. Results from the Framingham Heart Study show that higher levels of blood pressure, even within the nonhypertensive range, impose increased rates of cardiovascular disease (Kannel, 2000a, b). A continuous graded increase in cardiovascular risk is observed as blood pressure increases, with no evidence of a threshold value. Most events arise not in the most severe cases, but mainly in those with high normal blood pressure (i.e., mild hypertension). Kannel (2000a) emphasized that systolic blood pressure exerts a strong influence on more serious cardiovascular events, as it is the primary cause of hypertension and its adverse cardiovascular sequelae. In addition to the small increases in blood pressure associated with Pb, Pb-associated effects on cardiovascular morbidity outcomes such as ischemic heart disease (Section 5.4.3.6) and mortality (Section 5.4.5) have been observed. The high correlation between blood pressure and clinical cardiovascular outcomes combined with the high prevalence of cardiovascular disease in the U.S. adult population translate into a large increase in the prevalence of conditions in the population. In addition, some groups within the population can be at greater risks for cardiovascular effects; as summarized in Chapter 6, there is evidence for increased cardiovascular effects based on race/ethnicity and several genetic markers. Overall, while some of the specific health endpoints that have been associated with Pb exposure are small physiological changes in an individual, these changes can represent substantial risk at the population level.

2.9.2 Air-Pb–to–Blood-Pb Relationships

The 1986 Pb AQCD described epidemiological studies of relationships between air Pb and blood Pb. Much of the pertinent earlier literature for children described in the 1986 Pb AQCD was included in a meta-analysis by Brunekreef (1984). Based on the studies available at that time, the 1986 Pb AQCD concluded that "the blood Pb versus air Pb slope β is much smaller at high blood and air levels." This is to say that the slope β was much smaller for occupational exposures where high blood Pb levels (>40 μg/dL) and high air Pb levels (much greater than 10 $\mu g/m^3$) prevailed relative to lower environmental

exposures which showed lower blood Pb and air Pb concentrations (<30 µg/dL and <3 µg/m^3). For those environmental exposures, it was concluded that the relationship between blood Pb and air Pb "…for direct inhalation appears to be approximately linear in the range of normal ambient exposures (0.1-2.0 µg/m^3)" (pp 1–98 of the 1986 Pb AQCD). In addition to the meta-analysis of Brunekreef (1984), more recent studies have provided data from which estimates of the blood Pb-air Pb slope can be derived for children (Table 2-6, Table 4-12). The range of estimates from these studies is 2-9 µg/dL per µg/m^3, which encompasses the estimate from the Brunekreef (1984) meta-analysis of (3-6 µg/dL per µg/m^3). Most studies have described the blood Pb-air Pb relationship as either log-log (Schnaas et al., 2004; Hayes et al., 1994; Brunekreef, 1984), which predicts an increase in the blood Pb-air Pb slope with decreasing air Pb concentration or linear (Hilts, 2003; Tripathi et al., 2001; Schwartz and Pitcher, 1989), which predicts a constant blood Pb-air Pb slope across all air Pb concentrations. These differences may simply reflect model selection by the investigators; alternative models are not reported in these studies.

The blood Pb-air Pb slope may also be affected in some studies by the inclusion of parameters (e.g., soil Pb) that may account for some of the variance in blood Pb attributable to air Pb. Other factors that likely contribute to the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources, which varied among individual studies. See Section 4.5 for a detailed discussion of studies that inform air Pb-to blood-Pb relationships.

Table 2-6 Summary of estimated slopes for blood Pb to air Pb relationships in children.

Reference	Study Methods	Model Description	Blood Pb–Air Pb Slope[a]
Brunekreef (1984)	**Location:** Various countries **Years:** 1974-1983 **Subjects:** Children (varying age ranges, n>190,000) **Analysis:** Meta analysis of 96 child populations from 18 study locations	**Model:** Log-Log **Blood Pb:** 5-76 µg/dL (mean range for studies) **Air Pb:** 0.1-24 µg/m^3 (mean range for studies)	**All children:** 4.6 (1.5)[b] **Children <20 µg/dL:** 4.8 (0.54)[c]
Hayes et al. (1994)	**Location:** Chicago, IL **Years:** 1974-1988 **Subjects:** 0.5-6 yr (n = 9,604) **Analysis:** Regression of quarterly median blood Pb and quarterly mean air Pb	**Model:** Log-Log **Blood Pb:** 10-28 µg/dL (quarterly median range) **Air Pb:** 0.05-1.2 µg/m^3 (quarterly mean range)	8.2 (0.62)[d]
Hilts et al. (2003)	**Location:** Trail, BC **Years:** 1989-2001 **Subjects:** 0.5-6 yr (Estimated n = 220-460, based on 292-536 blood Pb measurements/yr with 75-85% participation). **Analysis:** Regression of blood Pb screening and community air Pb following upgrading of a local smelter	**Model:** Linear Blood Pb: 4.7-11.5 µg/dL (annual geometric mean range) **Air Pb:** 0.03-1.1 µg/m^3 (annual geometric mean range)	7.0 (0.48)[e]
Schwartz and Pitcher (1989), U.S. EPA (1986a)	**Location:** Chicago, IL **Years:** 1976-1980 **Subjects**: Black children, 0-5 yr (n = 5,476) **Analysis:** Multivariate regression of blood Pb with mass of Pb in gasoline (derived from gasoline consumption data and Pb concentrations in gasoline for the U.S.)	**Model:** Linear **Blood Pb:** 18-27 µg/dL (mean range)[f] **Air Pb:** 0.36-1.22 µg/m^3 (annual maximum quarterly mean)[h]	8.6 (0.75)[g]
Tripathi et al. (2001)	**Location:** Mumbai, India (multiple residential locations) **Years:** 1984-1996 **Subjects:** 6-10 yr (n = 544) **Analysis:** Regression of residential location-specific average blood Pb and air Pb data	**Model:** Linear **Blood Pb:** 8.6-14.4 µg/dL (GM range for residential locations) **Air Pb:** 0.11-1.18 µg/m^3 (GM range for residential locations)	3.6 (0.45)[i]

[a]Slope is predicted change in blood Pb (µg/dL per µg/m^3) evaluated at ± 0.01 µg/m^3 from central estimate of air Pb for the study (shown in parentheses). The central estimate for the Brunekreef (1984) study, is the median of air Pb concentrations, since it was a meta-analysis; for all other studies the mean is presented. For multiple regression models, this is derived based only on air Pb coefficient and intercept. Depending on the extent to which other variables modeled also represent air Pb, this method may underestimate the slope attributable to air pathways. In single regression models, the extent to which non-modeled factors, unrelated to air Pb exposures, exert an impact on blood Pb that co-varies with air Pb may lead to the slope presented here to over represent the role of air Pb.

[b]$\ln(PbB) = \ln(PbA) \times 0.3485 + 2.853$

[c]$\ln(PbB) = \ln(PbA) \times 0.2159 + 2.620$

[d]$\ln(PbB) = \ln(PbA) \times 0.24 + 3.17$

[e]$PbB = PbA \times 7.0$

[f]Observed blood Pb values not provided; data are for regressed adjusted blood Pb.

[g]$PbB = PbA \times 8.6$

[h]Based on data for the U.S. [1986 Pb AQCD, (U.S. EPA, 1986a)].

[i]$PbB = Pb A \times 3.6$

GM, geometric mean; GSD, geometric standard deviation; PbB, blood Pb concentration (µg/dL); PbA, air-Pb concentration (µg/m^3)

2.9.3 Concentration-Response Relationships for Human Health Effects

Concentration response (C-R) relationships have been examined most extensively in studies of neurodevelopmental effects in children. Although relatively few studies examined the shape of the concentration-response relationship between Pb in blood or bone and effects in adults, several recent studies of adult endpoints (i.e., cognitive function, cardiovascular and mortality effects) add to the evidence. Some of the populations examined (e.g., NHANES, NAS) are likely to have had higher past than recent Pb exposure. Other populations (e.g., worker populations) studied have ongoing exposure to Pb. As described elsewhere in the document (Sections 4.3, 5.3, 5.4, and 5.5), the interpretation of the study findings depends on the exposure history and the choice of the biomarker in the context of what is known about that exposure history. There is uncertainty regarding the frequency, duration, timing and level of exposure contributing to the blood Pb or bone Pb levels in the adult populations studied.

Cognitive and Behavioral Effects in Children

With each successive Pb AQCD and supplement, the epidemiologic and toxicological study findings show that progressively lower blood Pb levels or Pb exposures are associated with cognitive deficits in children (Section 5.3.13). For example, effects were observed in association with blood Pb levels in the range of 10-15 µg/dL in the 1986 Addendum (U.S. EPA, 1986c) and 1990 Supplement (U.S. EPA, 1990a), and 10 µg/dL and lower in the 2006 Pb AQCD (U.S. EPA, 2006b). No evidence of a threshold for the effects of Pb on neurodevelopmental effects has been reported across the range of blood Pb levels examined in epidemiologic studies.

Compelling evidence for a larger decrement in cognitive function per unit increase in blood Pb among children with lower mean blood Pb concentrations compared to children with higher mean blood Pb concentrations was presented in the 2006 Pb AQCD. This evidence was based on the international pooled analysis of seven prospective cohort studies by Lanphear et al. (2005), a subsequent reanalysis of these data focusing on the shape of the concentration response function (Rothenberg and Rothenberg, 2005), and several individual studies (Section 5.3.16, Figure 5-16, and Table 5-16).

Attenuation of concentration-response (C-R) relationships at higher exposure or dose levels has been reported in the occupational literature for a range of exposures. Reasons proposed to explain the attenuation include greater exposure measurement error and saturation of biological mechanisms at higher levels as well depletion of the pool of susceptible individuals at higher exposure levels (Stayner et al., 2003). Explanations specific to nonlinear relationships observed in studies of Pb exposure in children include

a lower incremental effect of Pb due to covarying risk factors such as low SES, poor caregiving environment, and higher exposure to other environmental factors (Schwartz, 1994), differential activity of mechanisms at different exposure levels, and confounding by omitted or misspecified variables. Review of the evidence did not reveal a consistent set of covarying risk factors to explain the differences in blood Pb IQ C-R relationship across high and low Pb exposure groups observed in epidemiologic studies. Nonlinear concentration-response relationships including U- or inverted U-shaped curves for various endpoints, including those related to cognitive impairment were demonstrated in the toxicological literature. However, these toxicological findings are distinct from epidemiologic findings of supralinear relationships in that some U- or inverted U-shaped relationships do not indicate Pb-induced impairments at higher exposure concentrations.

The supralinear relationship reported in multiple prospective studies does not provide evidence supporting a threshold for Pb-associated cognitive function decrements. As detailed in Section 5.3.13, higher age 2 year blood Pb levels were associated with FSIQ decrements in children aged 10 years whose blood Pb levels were in the range of 1.0-9.3 µg/dL, e.g.(Bellinger, 2008). Supporting evidence was provided by Pb-associated decrements in academic performance observed in fourth grade children with earlier childhood blood Pb levels 2 µg/dL versus 1 µg/dL (Miranda et al., 2009; 2007a). The lack of a reference population with blood Pb levels reflecting pre-industrial Pb exposures limits the ability to identify a threshold in the current population. Toxicological studies showed that lower Pb exposures (e.g., 50 ppm in drinking water) induced learning and memory impairments in animals compared to control exposures or higher Pb exposures (e.g., 150 ppm). Additional toxicological evidence suggests that mechanisms may be differentially activated at lower and higher Pb exposures, and reduced long-term potentiation (LTP) and hippocampal glutamate release with lower Pb exposures may provide explanation for impaired learning and memory with lower Pb exposures.

Studies of Pb Effects in Adults

The shape of the C-R function (e.g., linear versus non-linear) was not examined in most studies of the association of Pb biomarkers with cognitive function in adults (Sections 5.3.2.7 and 5.3.13). Log-linear models were used to fit the data in NHANES analyses. Nonlinearity in the relationship between bone Pb and cognitive function among participants in the BMS and NAS cohorts was examined with the use of quadratic terms, penalized splines, or visual inspection of bivariate plots. There was some evidence for nonlinearity in prospective analyses of the NAS cohort (Figure 5-8 and Figure 5-9), but not all results indicated a larger decrement in cognitive function per unit increase in bone Pb level in lower bone Pb groups. In the BMS cohort, statistical tests of nonlinearity

indicated that a linear model fit the relationship between tibia Pb level and various tests of cognitive function.

A meta-analysis of human studies found that each doubling of blood Pb level (between 1 and >40 μg/dL measured concurrently in most studies of adults for which past exposures were likely higher than current exposures) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP (Nawrot et al., 2002). In this analysis, effect sizes were adjusted for the purpose of pooling them depending on whether a linear or log (common or natural) linear model was used. The functional form of the C-R relationship was examined in few individual studies of cardiovascular effects (Section 5.4.2.1). Weaver (2010), reported that a logarithmic function of blood Pb level better described data from a cohort of Korean workers than the linear form. Only a small number of studies that focused on Pb-induced hypertension in experimental animals have included more than two exposure concentrations; however these studies appear to have a supralinear concentration-response (Figure 5-21).

Studies investigating both all-cause and cardiovascular mortality report both linear and non-linear relationships (Section 5.4.5). Although associations a re consistently reported, findings regarding the shape of C-R relationship between blood Pb level and mortality in NHANES analyses were mixed. In the NAS cohort, C-R relationships between bone Pb and mortality were approximately linear for patella Pb on the log(heart rate [HR]) scale for all cardiovascular disease (CVD), but appear nonlinear for IHD (Weisskopf et al., 2009). It is important to note the wide confidence limits, which increase uncertainty at the lower and upper bounds of patella Pb levels. The strongest associations were observed between mortality and baseline patella Pb concentration while tibia Pb levels were more weakly associated with CVD mortality. Tibia bone Pb level is thought to reflect a longer cumulative exposure period than is patella bone Pb level because the residence time of Pb in trabecular bone is shorter than that in cortical bone.

2.9.4 Patterns of Pb Exposure and Neurodevelopmental Deficits in Children

Blood Pb, which is the most common biomarker of exposure used in epidemiologic studies of children, is an integrative measure that does not allow aspects of exposure such as frequency, timing, duration, and level to be distinguished. Exposure metrics based on blood Pb measurements at different ages in childhood are typically highly correlated. Analyses of serial blood Pb concentrations measured in longitudinal epidemiologic studies find relatively strong correlations (e.g., r = 0.5-0.8) among each child's individual blood Pb concentrations measured after 6-12 months of age. (Section 4.3.2).

Consequently, it is difficult to distinguish the relative importance of various exposure metrics in both cross-sectional and longitudinal studies of the effect of Pb in children.

As discussed in Section 4.3.5, blood Pb may reflect both recent exposures as well as past exposures since Pb is both taken up by and released from the bone. The relative proportion of blood Pb from recent versus past exposure is uncertain in the absence of specific information about the pattern of exposure contributing to observed blood Pb levels. This uncertainty is greater in adults and older children than in young children who do not have lengthy exposure histories. Several lines of evidence, which are summarized below, inform the interpretation of epidemiologic studies of young children with regard to the patterns of exposure that contribute to observed health effects. See Section 5.3.12 for additional details on specific studies that form the evidence base on lifestage of exposure and neurodevelopmental deficits.

Epidemiologic studies consistently show that blood Pb levels measured during lifestages throughout childhood, as well as averaged over multiple years during childhood, are associated with cognitive function decrements and increases in attention-related behaviors (Section 5.3.12). Evidence in animals also indicates that Pb exposures during multiple lifestages, including prenatal only, prenatal plus lactational, postnatal only, lifetime are observed to induce impairments in learning in rodents and monkeys (Rice, 1992b, 1990; Rice and Gilbert, 1990b). These findings are consistent with the understanding that the nervous system continues to develop (i.e., synaptogenesis and synaptic pruning remains active) throughout childhood and into adolescence.

The international pooled analysis of seven prospective studies found that increments in concurrent and peak blood Pb levels were associated with a decrease in FSIQ measured between ages 5 and 10 years (Lanphear et al., 2005). In individual studies, postnatal (early childhood and concurrent) blood Pb levels are also consistently associated with cognitive function decrements in children and adolescents (Figure 5-2, Table 5-3, Table 5-14).

Although concurrent blood Pb levels in children are highly affected by recent exposure, they are also influenced by past/prenatal exposure due to the rapid growth-related bone turnover in children. Thus, concurrent blood Pb level in children also may reflect cumulative dose (Section 4.3.5.1). Animal toxicology data indicate that developmental Pb exposures creating steady-state blood-Pb concentrations of ~10 μg/dL result in behavioral impairments that persist into adulthood in rats and monkeys. In rats, neurobehavioral deficits that persisted well into adulthood were observed with prenatal, preweaning, and postweaning Pb exposure. In monkeys, such impaired learning and short-term memory at when tested at 7 to 8 years (Rice and Karpinski, 1988) and impairments in attention when tested at 9 to 10 years (Gilbert and Rice, 1987) were observed with Pb exposure

that did not begin until postnatal day 400 and that produced peak blood-Pb levels <15 μg/dL and steady-state levels ~11 μg/dL, indicating that postnatal juvenile Pb exposures were sufficient to produce neurodevelopmental deficits.

Pb can cross the placenta to affect the developing fetal nervous system and fetal Pb exposure can occur from recent maternal exposure or from mobilization of bone Pb stores from past exposures (Section 4.2.2.4). In very young children, ages <2 years, decrements in mental development, as assessed with MDI, was associated with higher prenatal (maternal and cord) and concurrent blood Pb levels (Section 5.3.2.2). Thus, both postnatal child and maternal Pb exposures may contribute to neurodevelopmental effects in children from infancy to age 2 years.

There is some evidence that the relative influence of maternal Pb levels on postnatal blood Pb level is substantially reduced soon after birth (Section 4.4). There was also a good correlation between child blood Pb level and child hand Pb loading ($R^2 = 0.70$) in a study following children living in a contaminated area, indicating the influence of concurrent Pb exposures on blood Pb during the early childhood years (Simon et al., 2007). In another study (Carbone et al., 1998) blood Pb levels of infants aged 6-12 months were significantly lower than their neonatal cord blood Pb levels (2.24 μg/dL versus 4.87 μg/dL). Among infants born with blood Pb levels of greater than 7 μg/dL, who were followed for a week, there was a dramatic drop in the blood Pb (Carbone et al., 1998).

2.9.5 Reversibility and Persistence of Neurotoxic Effects of Pb

The 2006 Pb AQCD concluded that the human and animal evidence suggest that the neurotoxic effects of Pb are not generally reversible (U.S. EPA, 2006b). Chelation studies in humans and animals show that chelation decreases total body Pb burden, but does not necessarily exert evident effects on Pb-induced cognitive deficits. For example, analysis of multi-center study data indicates that medical interventions involving chelation therapy (e.g., Succimer use) do not fully reverse cognitive deficits associated with early Pb exposure (Liu et al., 2002).

The persistence of neurodevelopmental effects from comparatively low-level Pb exposure was also considered in the 2006 Pb AQCD (U.S. EPA, 2006b), with some evidence suggesting that the effects of Pb on neurodevelopmental outcomes persisted into adolescence and young adulthood. The toxicological evidence continues to support a range of effects with prenatal and early postnatal Pb exposures that persist to adulthood (Sections 5.3.2.3 and 5.3.3.1). A number of mechanisms, including changes in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and

neurotransmitter function have been identified that provide biological plausibility for epidemiologic and toxicological findings of persistent cognitive and behavioral effects that result from Pb exposures during prenatal and early childhood periods. Furthermore, the normal dynamic and rapid rate of development that occurs early in life in the CNS makes insults early in life especially problematic in that they can permanently change the trajectory of brain development such that there are little or no compensatory pathways to replace the lost potential for proper brain development (Bayer, 1989).

The persistence of effects appears to depend on the duration and window of exposure as well as other factors that may affect an individual's ability to recover from an insult. There is evidence that some cognitive effects of prenatal Pb exposure may be transient and that recovery is greater among children reared in households with more optimal caregiving characteristics and in children whose concurrent blood Pb levels were low (Bellinger et al., 1990); the animal toxicology literature supports these findings using studies of Pb-exposed animals that live in enriched environments.

Toxicological studies in the 2006 Pb AQCD highlighted the importance of Pb exposure during early life in promoting Alzheimer's-like pathologies in the adult rodent brain, with Pb-induced neurodegeneration and formation of neurofibrillary tangles in aged animals in which blood Pb levels had returned to control levels after an earlier life Pb exposure (U.S. EPA, 2006b). Sensitive windows of early life Pb exposure or a Pb biomarker and have been associated with persistent changes in adulthood as demonstrated with animal models of neurodegeneration, i.e., neurofibrillary tangle formation. These effects are not reflective of concurrent blood-Pb levels at the age of manifestation of the pathology but instead are associated with an earlier life Pb exposure.

2.9.6 Populations Potentially At-Risk for Health Effects

The NAAQS are intended to protect public health with an adequate margin of safety. In so doing, protection is provided for both the population as a whole and those groups potentially at increased risk for health effects from exposure to the air pollutant for which each NAAQS is set (Preface to this ISA). To facilitate the identification of populations at increased risk for Pb-related health effects, studies have evaluated various factors that may contribute to susceptibility and/or vulnerability to Pb. These characteristics include various factors, such as genetic background, race and ethnicity, sex, age, diet, pre-existing disease, SES, and characteristics that may modify exposure or the response to Pb. Table 2-7 (Table 6-5) provides an overview of the factors examined as potentially increasing the risk of Pb-related health effects based on the recent evidence integrated

across disciplines. They are classified according to the criteria discussed in the introduction to Chapter 6.

Table 2-7 Summary of evidence for factors that potentially increase the risk of Pb-related health effects.

Factor Evaluated	Classification
Childhood (Sections 6.2.1, 6.3.1)	Adequate
Older Adulthood (Sections 6.2.1.2, 6.3.1.2)	Suggestive
Sex (Sections 6.2.2, 6.3.2)	Suggestive
Genetics (Sections 6.3.3)	Suggestive
Pre-existing Disease[a] (Section 6.3.4)	Suggestive
Smoking Status (Section 6.3.5)	Inadequate
Socioeconomic Status (SES) (Sections 6.2.4, 6.3.6)	Suggestive
Race/Ethnicity (Sections 6.2.3, 6.3.7)	Adequate
Proximity to Pb Sources (Section 6.2.5)	Adequate
Residential Factors (Section 6.2.6)	Adequate
Body Mass Index (BMI) (Section 6.3.8)	Inadequate
Alcohol Consumption (Section 6.3.9)	Inadequate
Nutrition (Section 6.3.10)	Adequate
Stress (Section 6.3.11)	Suggestive
Maternal Self-Esteem (Section 6.3.12)	Inadequate
Cognitive Reserve[a] (Section 6.3.13)	Inadequate
Other Metals (Section 6.3.14)	Suggestive

[a]Possible mediator

In consideration of the evidence base as a whole (e.g., stratified and longitudinal analyses) and integrating across disciplines of toxicokinetics, exposure, and health, there is adequate evidence to conclude that children are an at-risk population. It is recognized that Pb can cross the placenta and affect the developing nervous system of the fetus (Section 4.2.2.4). Children may have increased exposure to Pb compared with adults because children's behaviors and activities (including increased hand-to-mouth contact, crawling, and poor hand-washing), differences in diets, and biokinetic factors. There is evidence of increased risk to the neurocognitive effects of Pb exposure during several lifestages throughout gestation, childhood, and into adolescence (Section 5.3.12). Findings from magnetic resonance imaging (MRI) studies indicate that normal brain

development remains dynamic throughout adolescence, and epidemiologic studies have linked concurrent blood Pb level (as well as other blood Pb metrics) in adolescents to decrements in cognitive function and delinquent or criminal behavior (Section 5.3.4). Delays in puberty onset (Section 5.8.1), and renal effects (Section 5.5.2.2), are also observed in association with concurrent blood Pb level in cross-sectional studies of adolescents. Since the populations of older children in these studies generally had higher past exposures, the current evidence does not clearly establish the link between a time and duration of exposure during adolescence and the observed health effects in the adolescent populations studied. Elevated biomarkers levels, which may be related to remobilization of stored Pb during bone loss and/or higher historical Pb exposures, are observed in older adults. Studies of older adults report inconsistent findings for effect measure modification of Pb-related mortality by age and no modification of other health effects studied. However, toxicological studies support the possibility of age-related differences in Pb-related health effects. The overall evidence, based on limited epidemiologic evidence but support from toxicological studies and differential exposure studies, is suggestive that older adults are potentially at risk of Pb effects. However, there are uncertainties related to the exposure profile associated with the effects in older populations.

The evidence regarding the other at-risk factors listed in the table above is summarized in detail in Section 6.4. Some studies suggest that males at some ages have higher blood Pb levels than comparably aged females; this was supported by stratifying the total sample of NHANES subjects. Sex-based differences appeared to be prominent among the adolescent and adult age groups but were not observed among the youngest age groups (1-5 years and 6-11 years). Studies of effect measure modification of Pb and various health endpoints by sex were inconsistent; although it appears that there are some differences in associations for males and females. This is also observed in toxicological studies. Overall, there is suggestive evidence to conclude that sex is a potential at-risk factor, with males, adolescents, and adults typically demonstrating higher blood Pb levels, although evidence regarding health outcomes is limited due to inconsistencies between whether males or females are at greater risk of certain outcomes.

Regarding race and ethnicity, recent data suggest that the difference in blood Pb levels between black and white subjects is decreasing over time, but black subjects still tend to have higher Pb body burden and Pb exposures than white subjects. Compared to whites, non-white populations were observed to be more at risk of Pb-related health effects. Studies of race/ethnicity provide adequate evidence that race/ethnicity is an at-risk factor based on the higher exposure observed among non-white populations and some modification observed in studies of associations between Pb levels and health effects. For example, Muntner et al. (2005) reported modification by race/ethnicity in an analysis of

hypertension among NHANES III participants. In comparisons of the highest quartile of blood Pb to the lowest, the odds ration for hypertension was 1.54 (95% CI: 0.99, 2.39) among Mexican Americans, 1.44 (95% CI: 0.89, 2.32) among Non-Hispanic Blacks and 1.10 (95% 0.87, 1.41) among Non-Hispanic Whites.

The gap between SES groups with respect to Pb body burden appears to be diminishing. However, biomarkers of Pb exposure have been shown to be higher among lower SES groups even in recent studies in which differences among SES groups have lessened. Studies of SES and its relationship with Pb-related health effects are few and report inconsistent finding regarding low SES as a potential at-risk factor. Overall, the evidence is suggestive that low SES is a potential at-risk factor for Pb-related health effects.

There is adequate evidence that proximity to areas with Pb sources, including areas with large industrial sources, is associated with increased Pb exposure. Relatively high concentrations of ambient air Pb have been measured near sources, compared with large urban areas without sources and high Pb exposures have been documented near Superfund sites. NHANES analyses report increased Pb biomarker levels related to increase house dust Pb levels, homes built after 1950, and renovation of pre-1978 homes. Thus, there is adequate evidence that residing in a residence with sources of Pb exposures will increase the risk of Pb exposure and associated health effects.

There is suggestive evidence to conclude that various genes potentially modify the associations between Pb and health effects. Epidemiologic and toxicological studies reported that ALAD variants may increase the risk of Pb-related health effects. Other genes examined that may also affect risk of Pb-related health effects were VDR, DRD4, GSTM1, TNF-α, eNOS, and HFE. Overall the interaction between genes and Pb exposure were examined in a small number of studies and these types of analysis are potentially vulnerable to type II error if multiple statistical tests are conducted. However, there may be a large potential impact of Pb exposure in specific at-risk populations carrying specific gene variants. For example, Scinicariello et al. (2010) found that Non-Hispanic white carriers of the ALAD2 genetic variant in the highest blood Pb quartile had a 2-fold higher risk of hypertension compared with ALAD1 homozygous individuals (OR=2.00 95%CI: 1.12, 3.55). No evidence of effect modification of the association of Pb with blood pressure by ALAD was observed in an occupational study of Korean Pb workers, however (Weaver et al., 2008). NAS subjects with the H63D polymorphism of the HFE gene an IQR had a larger Pb-associated increase in pulse pressure compared to those with the C282Y variant [i.e., 3.3 mmHg increase (95%CI: 0.16, 6.46) versus an 0.89 mmHg increase (95%CI 0-5.24) (Zhang et al., 2010a)].

Diets sufficient in minerals such as calcium (Ca^{2+}), iron (Fe), and zinc (Zn) offer some protection from Pb exposure by preventing or competing with Pb for absorption in the GI

tract. Additionally, those with iron deficiencies were observed to be an at-risk population for Pb-related health effects in both epidemiologic and toxicological studies. Thus, there is adequate evidence across disciplines that some nutritional factors contribute to a population being at increased risk. Other nutritional factors, such as Ca^{2+}, Zn, and protein intake, demonstrated the potential to modify associations between Pb and health effects in toxicological studies. Recent epidemiologic studies of these factors were either not performed or observed no effect modification. Folate was also examined in an epidemiologic study of birth size but no interaction was reported between Pb and folate.

There was suggestive evidence for several other factors as potentially increasing the risk of Pb-related health effects: pre-existing diseases/conditions, stress, and co-exposure with other metals. Pre-existing diseases/conditions have the potential to affect the risk of Pb-related health effects. Recent epidemiologic studies did not support modification of associations between Pb and health endpoints (i.e., mortality, HRV) by the prevalence of diabetes; however, past studies have found individuals with diabetes to be an at-risk population with regard to renal function. Studies of Pb levels and both renal effects and heart rate variability demonstrated greater odds of the associations among hypertensive individuals compared to those that are normotensive. Stress was evaluated as a factor that potentially increases the risk of Pb-related effects on cognitive function in adults and hypertension and although limited by the small number of epidemiologic studies, increased stress was observed to exacerbate the effects of Pb. Toxicological studies supported this finding. High levels of other metals, such as Cd and Mn, were observed to result in greater effects for the associations between Pb and various health endpoints (e.g., renal function, cognitive function in children) but overall the evidence was limited. Finally, there was inadequate evidence to conclude that smoking, BMI, alcohol consumption, maternal self-esteem, and cognitive reserve are potential at-risk factors due to limited quantities of studies regarding their effect on Pb-related health outcomes.

2.9.7 Ecological Effects and Corresponding Pb Concentrations

There is limited evidence to relate ambient air concentrations of Pb to levels of deposition onto terrestrial and aquatic ecosystems and to subsequent movement of atmospherically-deposited Pb through environmental compartments (e.g., soil, sediment, water, biota). The proportion of observed effects of Pb attributable to Pb from atmospheric sources is difficult to assess due to a lack of information not only on bioavailability, as affected by the specific characteristics of the receiving ecosystem, but also on deposition, and on kinetics of Pb distribution in ecosystems in long-term exposure scenarios. Therefore, the connection between air concentration and ecosystem exposure

continues to be poorly characterized for Pb, and the contribution of atmospheric Pb to specific sites is not clear.

Furthermore, the level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems, due to the influence of other environmental variables on both Pb bioavailability and toxicity, and also to substantial species differences in Pb susceptibility. Current evidence indicates that Pb is bioaccumulated in biota; however, the sources of Pb in biota have only been identified in a few studies, and the relative contribution of Pb from all sources is usually not known. There are large differences in species sensitivity to Pb, and many environmental variables (e.g., pH, organic matter) determine the bioavailability and toxicity of Pb.

2.10 Summary

Table 2-8 characterizes the evidence in the 2006 Pb AQCD (U.S. EPA, 2006b) and previous assessments and compares it to the evidence evaluated in the current assessment. Evidence regarding both the health and ecological effects of Pb are summarized. The purpose of the table is to highlight the extent to which recent evidence may contribute to current conclusions. The critical assessment of body of evidence as a whole, however, is discussed in Chapter 5 and Chapter 7 of this document, and summarized in Sections 2.6 and 2.7. For the health effects evidence, population mean blood Pb levels are included for studies of children, along with the mean age or range of ages included in the study, because there is less uncertainty regarding the exposure patterns contributing to the mean blood Pb levels reported in studies of younger populations. With regard to ecological effects, evidence pointing to responses in species at ambient or near ambient concentrations is highlighted in the table.

Table 2-8 Summary of evidence from epidemiologic, animal toxicological and ecological studies on the effects associated with exposure to Pb.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Health Outcomes:		
Nervous System Effects		
Cognitive Function in Children	The "overall weight of the available evidence provides clear substantiation of neurocognitive decrements being associated in young children with blood-Pb concentrations in the range of 5-10 µg/dL, and possibly lower". Prenatal, early childhood, lifetime average, and concurrent blood Pb levels were associated with decrements in IQ, learning and memory; however, concurrent blood Pb level was the strongest predictor.	Recent epidemiologic studies in children continue to demonstrate associations of concurrent blood Pb level with IQ decrements; most recent evidence describes associations of concurrent blood Pb levels with decrements in cognitive abilities related to memory, executive function, and academic performance. These associations were found in populations with mean blood Pb levels 2-7 µg/dL.
Attention-Related Behavioral Problems in Children	Several epidemiologic studies reported associations between blood and tooth Pb levels and inattention and impulsivity in children ages 8-17 years and young adults 19-20 years. Most studies examined blood Pb levels measured earlier in childhood (means ~11-14 µg/dL), tooth Pb, or bone Pb. The few studies of concurrent blood Pb levels did not find associations with inattention in children ages 5 years. There were no studies specifically examining ADHD diagnosis. Uncertainty remained regarding whether Pb exposure was an independent predictor of neurobehavioral effects. Prenatal and postnatal Pb exposure was found to reduce ability to inhibit inappropriate responding and increase distractibility in animals.	Recent studies in children continue to support associations of blood Pb levels with inattention and hyperactivity in children ages 8-17 years. In several recent studies, associations were found with concurrent blood Pb in populations with mean blood Pb levels 1–5 µg/dL; however, the influence of higher past Pb exposures in these older children cannot be excluded. A few case-control studies found higher concurrent blood Pb levels in children with ADHD.
Internalizing Behaviors in Children	Several prospective studies reported associations of concurrent, childhood average, tooth, and bone Pb levels with parent or teacher ratings of withdrawn behavior, depression-like symptoms, fearfulness, and anxiety in children ages 3-13 years.	The few recent available studies found associations between concurrent blood Pb level and higher ratings of internalizing behaviors in children ages 3-13 years but had limited implications because of lack of representativeness of populations and/or limited consideration for potential confounding,
Misconduct in Children and Young Adults	Several epidemiologic studies reported associations between Pb exposure and conduct problems as rated by parents and teachers and criminal offenses in children, adolescents, and young adults. Most studies examined blood Pb levels measured earlier in childhood (means ~10 µg/dL), tooth Pb, or bone Pb. There was little examination of concurrent blood Pb levels.	Recent studies in children continue to support associations of parent and teacher ratings of conduct problems with early childhood blood Pb levels and provide new evidence for concurrent blood Pb levels. Additional follow-up of previous cohorts to older ages, support associations of early childhood blood Pb levels or tooth Pb levels with criminal offenses in adults ages 19-24 years.
Sensory Function Decrements in Children	The selective action of Pb on retinal rod cells and bipolar cells (e.g., ERG effects) is well documented in earlier AQCDs. Developmental Pb exposure reduced visual acuity in animals. There was coherence between the extensive animal and the limited available human literature reporting associations between concurrent blood Pb levels (population means 7-12 µg/dL) and increased hearing thresholds in children.	The few available recent epidemiologic studies on sensory organ function in children examined children with high blood Pb levels (means >30 µg/dL) and did not consider potential confounding. Early postnatal Pb exposure of monkeys (blood Pb level 35-40 µg/dL increased hearing thresholds and decreased visual acuity. Retinal effects were found in male rodents with gestation/early postnatal Pb exposure producing lower blood Pb levels (~12 µg/dL) than those at which effects had been previously reported.
Motor Function Decrements in Children	A small number of studies indicated associations of earlier childhood average, lifetime average, and concurrent blood Pb levels (means: 5-12 µg/dL) with poorer fine and motor function in children ages 4-17 years. The few toxicological studies did not consistently find Pb-induced impairments in balance and coordination in animals with blood Pb levels >60 µg/dL.	The few recent epidemiologic studies did not consistently find associations between concurrent blood Pb level and decrements in fine motor function. A toxicological study found poorer balance in male mice with gestational plus lactational Pb exposure (blood Pb level: 33-42 µg/dL).

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Cognitive Function Decrements in Adults	Among environmentally-exposed adults, bone Pb levels but not blood Pb levels were associated with poorer cognitive performance. These findings point to an effect of long-term cumulative Pb exposure.	Recent studies support previous evidence. Recent prospective studies provide new evidence of associations of bone Pb levels with subsequent declines in cognitive function in environmentally-exposed adults over 3-4 year periods. However, as these outcomes are observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations
Psychopathological Effects in Adults	Environmentally-exposed adults were not widely examined; however a study found associations of concurrent blood and tibia Pb level with self-reported symptoms of depression and anxiety in men. Several studies found higher prevalence of symptoms related to mood disorders and anxiety in Pb-exposed workers with mean blood Pb levels 15-38 µg/dL.	Concurrent blood Pb levels were associated with symptoms of major depressive disorder and general anxiety disorder among men and women participating in NHANES.
Sensory Function Decrements in Adults	A few studies found blood Pb level or cumulative Pb exposure duration to be associated with increased hearing thresholds and hearing loss in Pb-exposed workers.	A prospective study found higher tibia Pb level to be associated with a faster rate of increase in hearing threshold in environmentally-exposed men over a median of 23 years.
Neurodegenerative Diseases	In the limited body of epidemiologic studies, occupational Pb exposure and brain Pb levels were not associated with Alzheimer's disease. Blood Pb levels were not consistently associated with Amyotrophic Lateral Sclerosis among environmentally-exposed adults. A few studies found associations between occupational Pb exposure and Parkinson's disease and blood Pb levels and essential tremor. Each study had sufficient limitations. Toxicological studies found Pb-induced neuronal cell death loss.	The few case-control studies reported associations of bone Pb levels with Parkinson's disease in environmentally-exposed adults and blood Pb levels with Amyotrophic Lateral Sclerosis and essential tremor. Limitations of previous studies apply to the recent evidence. Recent toxicological evidence suggests that early-life, not adult-only Pb exposure may be associated with neurodegeneration in adult animals.
Cardiovascular Effects		
Hypertension	A meta-analysis of numerous epidemiologic studies estimated that a doubling of blood Pb level (e.g., from 5 to 10 µg/dL) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP." Epidemiologic studies consistently demonstrated associations between Pb and incidence of hypertension with suggestive evidence that bone Pb may be associated with hypertension. Animal studies demonstrated that long-term exposure to Pb resulted in hypertension that persisted after cessation of exposure.	Recent epidemiologic and toxicological studies continue to support associations between long-term Pb exposure and increased BP. Associations of increased BP with blood and bone Pb concentrations are observed in populations with lower mean blood Pb levels. Recent studies, including those using bone Pb as a metric of cumulative exposure, continue to demonstrate associations of hypertension with Pb levels in adults at lower population Pb concentrations. Recent studies have emphasized the interaction of cumulative exposure to Pb with other factors including stress.
Subclinical Atherosclerosis	One NHANES analysis reported an association of blood Pb with PAD	Limited evidence for Pb-induced subclinical atherosclerosis, including one high-quality epidemiologic study that reports an increasing trend in the odds of PAD and concurrent blood Pb level in adults. Recent toxicological studies describe a plausible biological mechanism.
Coronary Heart Disease	The evidence for an association of Pb with cardiovascular mortality was limited but supportive. A few cross-sectional studies indicated associations between Pb biomarker levels and increased risk of CHD outcomes (i.e., MI and left ventricular hypertrophy).	Recent studies address limitations of previous studies and provide additional evidence for an association of Pb with cardiovascular mortality in adults. Specific causes of mortality that were associated with Pb could be related to increased BP and hypertension.
Cerebrovascular Disease	No evidence available on the risk of cerebrovascular disease from Pb exposure.	Limited, mixed evidence for increased risk of mortality from stroke.
Renal Effects		
Reduced Kidney Function	Circulating and cumulative Pb was associated with longitudinal decline in renal function in adults. Toxicological studies demonstrated that initial accumulation of absorbed Pb occurred primarily in the kidneys and noted a hyperfiltration phenomenon during the first 3 months of exposure, followed by decrements in kidney function.	Recent epidemiologic and toxicological studies evaluated in the current review support or expand upon the strong body of evidence indicating that Pb exposure is associated with kidney dysfunction (e.g., lower creatinine clearance, higher serum creatinine, and lower GFR) in nonoccupationally-exposed adults.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Immune System Effects		
Increases in Atopic and Inflammatory Conditions	**Children**:	
	Several epidemiologic studies suggested that Pb exposure may be associated with effects on cellular and humoral immunity in children. The principal effects demonstrated were decreases in T cell abundance and increases in serum immunoglobulin E (IgE) levels with concurrent blood Pb levels >10 µg/dL. Toxicological evidence supported these findings with extensive evidence for prenatal and early postnatal Pb exposures skewing toward Th2 cytokine production and affecting downstream events such as increases in IgE and inflammation Several toxicological studies found a Pb-induced shift to Th2 cytokine production and a hyperinflammatory phenotype of macrophages in animals with long-term (>4 weeks) prenatal or postnatal Pb exposure.	Recent studies in children added to the evidence for associations of blood Pb levels with asthma, allergy, and IgE. The consistency and coherence of findings among related immune effects that support a shift from a Th1 to a Th2 phenotype supports the biological plausibility for epidemiologic observations of associations with asthma, allergy and inflammation-related effects in other organ systems.
	Adults:	
	Pb exposure-associated immune effects were not widely examined in environmentally-exposed adults.	A small body of recently available studies provide new evidence for increases in cytokines and other indicators of inflammation in association with higher concurrent blood Pb level. Associations were observed in populations with a wide range of mean concurrent blood Pb levels (3-22 µg/dL). However, as these outcomes are observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations. A few available toxicological studies find Pb-associated increases in cytokines and effects on dendritic cells in adult mice.
Decreases in Host Resistance	Toxicological evidence demonstrated Pb-induced increases in bacterial and viral infection and suppressed DTH in animals. These effects were supported by extensive evidence for prenatal and early postnatal Pb exposures decreasing Th1 cytokine production, for short-term prenatal Pb exposure decreasing nitric oxide production by macrophages), and for long-term (>4 weeks) exposure Pb exposure inducing a hyperinflammatory phenotype of macrophages in adult animals. A few epidemiologic studies found higher prevalence of respiratory infections in association with higher blood Pb levels in children and occupational Pb exposure in adults; however, studies did not consider potential confounding. In the large body of studies in occupationally-exposed adults, the most consistent findings were reduced neutrophil functionality in workers with blood Pb levels >30 µg/dL. Environmentally-exposed adults were not widely examined.	A small body of recent studies supports previous findings of decreased bacterial resistance and decreased IFN-γTh1 cytokine production in animals and blood-Pb associated decreases in host resistance in children. Epidemiologic evidence is limited to an ecological study that lacked consideration for potential confounding.
Autoimmunity	A small number of toxicological studies found that prenatal and postnatal Pb treatment, several by i.p. injection, increased generation of auto-antibodies. A study found higher auto-antibodies to neural proteins in Pb-exposed workers with blood Pb levels 10-40 µg/dL	A recent toxicological study provided indirect evidence by showing Pb-induced increases in the activation of neo-antigen specific T cells, which have the potential to induce formation of auto-antibodies.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Hematologic System		
Red Blood Cell Function and Heme Synthesis	**Children:**	
	Pb exposure was associated with disruption in heme synthesis with increases in blood Pb levels of approximately 20 µg/dL sufficient to halve ALAD activity and inhibit ferrochelatase. Risk of clinical anemia in children becomes apparent at high blood Pb levels: 10% probability of anemia was estimated to be associated with ~20 µg/dL Pb at 1 year of age, 50 µg/dL at 3 years of age, and 75 µg/dL at 5 years of age.	Recent epidemiologic studies provide strong evidence that exposure to Pb is associated with numerous deleterious effects on the hematological system in children, including altered hematological parameters (Hb, MCV, MCH, RBC count), perturbed heme synthesis mediated through decreased ALAD and ferrochelatase activities, and oxidative stress.
	Adults:	
	Pb exposure was associated with disruption in heme synthesis with increases in blood Pb levels of approximately 20 µg/dL sufficient to halve ALAD activity and inhibit ferrochelatase. Exposures to Pb resulting in blood concentrations <40 µg/dL appear to be tolerated without decreases in blood hemoglobin or hematocrit, however changes in erythropoiesis do occur at these blood levels.	Recent epidemiologic studies provide strong evidence exposure to Pb is associated with numerous deleterious effects on the hematological system, including altered hematological parameters (Hb, MCV, MCH, RBC count), perturbed heme synthesis mediated through decreased ALAD and ferrochelatase activities, decreased erythropoiesis, and oxidative stress.
Developmental and Reproductive Effects		
Development	Epidemiologic studies reported effects including delayed puberty in girls. Animal toxicological studies reported Pb-associated developmental effects on teeth, sensory organs, the GI system, the liver, and postnatal growth. Delayed puberty was also observed in both male and female populations in animal toxicology studies showing associations with dam blood Pb levels of ~40 µg/dL and pup blood Pb levels of 26 µg/dL.	Recent toxicological and epidemiologic studies provide strong evidence for delayed onset of puberty in males and females. Most studies found delayed onset of puberty was among children ages 6-18 years with mean/median blood Pb levels less than 5 µg/dL. These findings were supported by studies in the toxicological literature showing effects on puberty onset at blood Pb levels of 3.5-13 µg/dL.
Birth Outcomes	Toxicological studies reviewed concluded that Pb exposure can increase fetal mortality and produce sublethal effects, smaller litters, reduced birth weight, and fewer implantation sites. Epidemiologic studies on preterm birth and low birth weight/fetal growth reported inconsistent findings. Epidemiologic studies reported the possibility of small associations between increased Pb exposure and birth defects, and toxicological studies demonstrated associations between exposure to high doses of Pb and increased incidences of teratogenic effects.	Recent toxicological and epidemiological studies have reported inconsistent findings for studies for birth defects, preterm birth, and low birth weight/fetal growth. A few well-conducted epidemiologic studies of preterm birth and low birth weight/fetal growth reported associations between increased Pb levels and decreased gestational age and birth weight/fetal growth.
Male Reproductive Function	Epidemiologic evidence suggested small associations between Pb exposure and male reproductive outcomes including perturbed semen quality and increased time to pregnancy. Associations between Pb exposure and male reproductive endocrine status were not observed in the occupational populations studied. Toxicological studies provided evidence that Pb produced effects on male and female reproductive junction and development and disrupts endocrine function.	Recent toxicological studies provide strong evidence for effects on sperm (blood Pb levels 34-37 µg/dL). Epidemiologic studies support the association observed in toxicological studies of Pb exposure and detrimental effects on sperm.
Female Reproductive Function	Toxicological studies reported that Pb exposure was associated with effects on female reproductive function that can be classified as alterations in female sexual maturation, effects on fertility and menstrual cycle, endocrine disruption, and changes in morphology or histology of female reproductive organs including the placenta. Epidemiologic studies on Pb and female reproductive function provided little evidence for an association between Pb biomarkers and effects on female reproduction and fertility.	Epidemiologic studies of Pb levels and hormones demonstrate associations but are inconsistent overall and there is a lack of large, well-conducted epidemiologic studies examining associations between Pb levels and fertility. Toxicological studies of Pb and effects on female reproduction demonstrate effects in some studies.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Cancer		
Cancer	Epidemiologic studies of highly exposed occupational populations suggest a relationship between Pb and cancers of the lung and the stomach; however the evidence is limited by the presence of various potential confounders, including metal co-exposures (e.g., to As, Cd), smoking, and dietary habits. The 2003 NTP and 2004 IARC reviews concluded that Pb and Pb compounds were probable carcinogens, based on limited evidence in humans and sufficient evidence in animals. Based on animal data and inadequate human data Pb and Pb compounds would be classified as likely carcinogens according to the EPA Cancer Assessment Guidelines for Carcinogen Risk Assessment.	The toxicological literature continues to provide the strongest evidence for Pb exposure and cancer with supporting evidence provided by the epidemiologic literature. Epidemiologic studies of cancer incidence and mortality reported inconsistent results.

Ecological/Welfare Effects:

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012 3rd Draft) Pb ISA
Developmental and Reproductive Effects	**Terrestrial Organisms:**	
	No information on reproduction in plants.	There is an insufficient number of studies that consider Pb effects on plant reproduction.
	Limited evidence in invertebrates and vertebrates.	Recent studies in a few taxa expand the evidence for Pb effects on developmental and reproductive endpoints for invertebrates and vertebrates at concentrations that generally exceed Pb levels in U.S. soils. In some organisms, exposure-dependent responses in development and reproductive outcomes are observed in experiments where exposure increases from background concentrations to concentrations found in heavily exposed sites near stationary sources. Data on terrestrial species is coherent with toxicological data from mammals in the context of human health research.
	Aquatic Organisms:	
	No reviewed studies on reproductive effects in aquatic plants. Reproductive and developmental effects reported in a few species of invertebrates at <50 µg Pb/L and in fish at <150 µg Pb/L	Recent evidence supports previous findings of reproductive and developmental effects of Pb in freshwater invertebrates and vertebrates and differential lifestage response at near ambient concentrations of Pb in some organisms.
Growth	**Terrestrial Organisms:**	
	Pb inhibits photosynthesis and respiration in plants. Limited evidence for growth effects in soil invertebrates, avian and mammalian consumers.	Recent studies support previous findings of Pb effects on plant growth, with some evidence for exposure-dependent decreases in the biomass of some plant species grown in Pb-amended or Pb-contaminated soil. Recent data for soil invertebrates supports previous evidence of increasing effects on growth with increasing exposure. Limited studies considered effects on growth on vertebrates.
	Aquatic Organisms:	
	Evidence for growth effects in algae, aquatic plants and aquatic invertebrates Most primary producers experience EC_{50} values for growth in the range of 1,000 to 100,000 µg Pb/L	The weight of the evidence continues to support growth effects of Pb in freshwater plants and invertebrates. Recent studies on growth in freshwater invertebrates find effects of Pb at lower concentrations than previously reported. Growth inhibition in one species of freshwater snail was observed at <4 µg Pb/L in juveniles. Lowest genus mean chronic value for Pb reported at 10 µg Pb/L in a freshwater mussel.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Survival	**Terrestrial Organisms:**	
	No information on mortality in plants. Effects of Pb on invertebrates and vertebrates include decreased survival. In terrestrial and avian species toxicity was observed in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight•day) (U.S. EPA, 2005b).	Recent studies in invertebrates and vertebrates support previous associations between Pb exposure and mortality.
	Aquatic Organisms:	
	No studies reviewed on mortality in plants at current concentrations of Pb in the environment. Pb impacted survival of some aquatic invertebrates at <20 µg Pb/L dependent upon water quality variables (i.e., DOC, hardness, pH). Range of 96-hour LC_{50} values in fathead minnow: 810->5,400 µg Pb/L	The weight of evidence continues to support Pb effects on survival of freshwater invertebrates and vertebrates and indicates that there are effects in a few species at lower concentrations than previously reported. Recent evidence for effects in a few freshwater invertebrates: at <20 µg Pb/L Recent evidence in freshwater fish for impacts to survival at <100 µg Pb/L dependent upon water quality parameters and lifestage. 96- hour LC_{50} values as low as 41 µg Pb/L in fathead minnows tested in natural waters from across the U.S.
Neurobehavioral Effects	**Terrestrial Organisms:**	
	Exposure to Pb in laboratory studies and simulated ecosystems may alter species competitive behaviors, predator-prey interactions, and contaminant avoidance behaviors.	Recent studies continue to support previous evidence that Pb exposure is associated with behavioral alterations. Recent studies identify possible molecular targets for Pb neurotoxicity in invertebrates and there is new evidence in a few invertebrate and vertebrate species for behavioral effects associated with Pb exposure (i.e., feeding and escape behaviors).
	Aquatic Organisms:	
	Exposure to Pb has been shown to affect brain receptors in fish and may alter avoidance behaviors and predator-prey interactions.	Recent studies continue to support previous evidence that Pb exposure is associated with behavioral alterations. Recent studies identify possible molecular targets for Pb neurotoxicity in fish and provide additional evidence for Pb effects on behaviors in freshwater organisms that may impact predator avoidance (swimming).
Hematological Effects	**Terrestrial Organisms:**	
	Pb effects on heme synthesis were documented in the 1986 Pb AQCD and continue to be studied in terrestrial biota. Changes in ALAD are not always related to adverse effects but may simply indicate exposure. The linkage between effects of Pb on blood parameters is well documented; however, the linkage between hematological indicators and ecologically relevant effects is less well understood.	Consistent with previous studies, the weight of the evidence in recent studies continues to support findings of Pb effects on heme synthesis and ALAD enzyme activity. Recent studies in birds near historical mining areas and altered serum profiles and blood cell counts in vertebrates provide evidence for additional species in which hematological endpoints are potentially affected by Pb.
	Aquatic Organisms:	
	In metal impacted habitats, ALAD is a recognized biomarker of Pb exposure. Changes in ALAD are not always related to adverse effects but may simply indicate exposure. In fish, Pb effects on blood chemistry have been documented with Pb concentrations ranging from 100 to 10,000 µg Pb/L.	Consistent with previous studies, the weight of the evidence in recent studies continues to support findings of Pb effects on ALAD and expands this evidence to additional species of bacteria, invertebrates, and vertebrates as well as in recent studies on altered blood cell counts in vertebrates. Additional field studies in aquatic bivalves report a correlation between Pb and ALAD activity.

Endpoint	Evidence in the 2006 Pb AQCD	Evidence in the (2012-3rd Draft) Pb ISA
Physiological Stress	**Terrestrial Organisms:**	
	Pb exposure may cause lipid peroxidation and changes in glutathione concentrations. There are species differences in resistance to oxidative stress.	Recent studies continue to support previous associations of Pb exposure with physiological stress. New evidence includes upregulation of antioxidant enzymes, production of reactive oxygen species and increased lipid peroxidation associated with Pb exposure in additional species of terrestrial plants, invertebrates and vertebrates. Experimental exposures increasing from background concentrations to concentrations found in heavily exposed sites near stationary sources.
	Aquatic Organisms:	
	Pb exposure associated with alterations in enzymes involved in physiological stress responses.	Recent studies continue to support previous associations of Pb exposure with physiological stress. New evidence in freshwater organisms includes upregulation of antioxidant enzymes, production of reactive oxygen species and increased lipid peroxidation associated with Pb exposure. Observed effects generally occurred at concentrations that typically exceed Pb levels in U.S. waters with limited evidence for effects associated with Pb at polluted sites.
Community and Ecosystem Level Effects	**Terrestrial Ecosystems:**	
	Effects of Pb difficult to interpret because of the presence of other stressors including metals. The 1986 Pb AQCD reported shifts toward Pb-tolerant communities at 500 to 1,000 mg Pb/kg soil. In the 2006 Pb AQCD, decreased species diversity and changes in community composition were observed in ecosystems surrounding former smelters.	Recent evidence for effects of Pb in soil microbial communities adds to the body of evidence for effects at higher levels of biological organization. In addition, effects of Pb uptake on reproduction, growth, and survival at the species level are likely to lead to effects at the population, community, and ecosystem level. However, most evidence for Pb toxicity to terrestrial biota is from single-species assays, and there are important uncertainties in generalizing from effects observed under small-scale, controlled conditions, up to effects at the ecosystem level of biological organization. .
	Aquatic Ecosystems:	
	Most evidence of community and ecosystem level effects is from near Pb sources, usually mining effluents. Effects of Pb difficult to interpret because of the presence of other stressors including metals. Generally, there is insufficient information available for single materials in controlled studies to permit evaluation of specific impacts on higher levels of organization (beyond the individual organism).	Recent evidence for Pb effects on sediment-associated and freshwater aquatic plant communities add to the body of evidence of effects at higher levels of biological organization. However, most evidence for Pb toxicity to aquatic biota is from single-species assays. Uncertainties exist in generalizing effects observed under small-scale, predicted conditions up to effects at the ecosystem-level however, uptake of Pb into aquatic organisms and subsequent effects on reproduction, growth, and survival at the species level are likely to lead to effects at the population, community, and ecosystem level.

3 AMBIENT LEAD: SOURCE TO CONCENTRATION

3.1 Introduction

This chapter reviews concepts and findings in atmospheric sciences that provide a foundation for the detailed presentation of evidence of Pb exposure and Pb-related health and ecological effects in subsequent chapters. Information in this chapter builds on previous Pb AQCDs using more recent data and studies. This includes new knowledge of Pb fate and transport, the latest developments in monitoring and analysis methodologies, and recent data describing Pb concentrations as a function of size range. The chapter focuses on Pb concentrations in the U.S. but includes non-U.S. studies to the extent that they are informative regarding current conditions in the U.S. Description of the chemical forms of Pb is not provided here, however, because this information is well established. The reader is referred to the 2006 Pb AQCD for a description of the chemical forms of Pb (U.S. EPA, 2006b).

Section 3.2 provides an overview of the sources of ambient air Pb. Section 3.3 provides a description of the fate and transport of Pb in air, soil, and aqueous media. Descriptions of Pb measurement methods, monitor siting requirements, and monitor locations are presented in Section 3.4. Ambient Pb concentrations, their spatial and temporal variability, size distributions of Pb-bearing particulate matter (PM), associations with copollutants and background Pb concentrations are characterized in Section 3.5. Concentrations of Pb in non-air media and biota are described in Section 3.6.

3.2 Sources of Atmospheric Pb

The following section reviews emissions estimates from the 2008 National Emissions Inventory (NEI) data from 2008 (U.S. EPA, 2011a), augmented with information on sources not included in the 2008 NEI version 2[1] and compares these emissions data with those from previous years. This section also reviews updated information from the peer-reviewed literature regarding sources of ambient Pb. Detailed information about processes for anthropogenic emissions and naturally-occurring emissions can be found in the 2006 Pb AQCD (U.S. EPA, 2006b). The papers cited herein generally utilized PM

[1] For presentation in this ISA, 2008 NEI, version 2 emissions estimates have been augmented with emissions estimates from the 2008 Toxics Release Inventory for a number of additional facilities that had been estimated to emit more than 0.5 tons per yr in 2005 and that are not included in the 2008 NEI, v2 for reasons related to the Pb emissions reporting threshold. This issue is described (and the facilities identified) as "NEI Identified Issue" #29 under "Point Data Category" in the 2008 NEI version 2 issues file accessible from ftp://ftp.epa.gov/EmisInventory/2008v2/doc/2008neiv2_issues.xlsx.

sampling data, because a majority of ambient airborne Pb readily condenses to PM. The mobile source category included combustion products from organic Pb antiknock additives used in piston-engine aircraft (hereafter referred to piston-engine aircraft emissions).

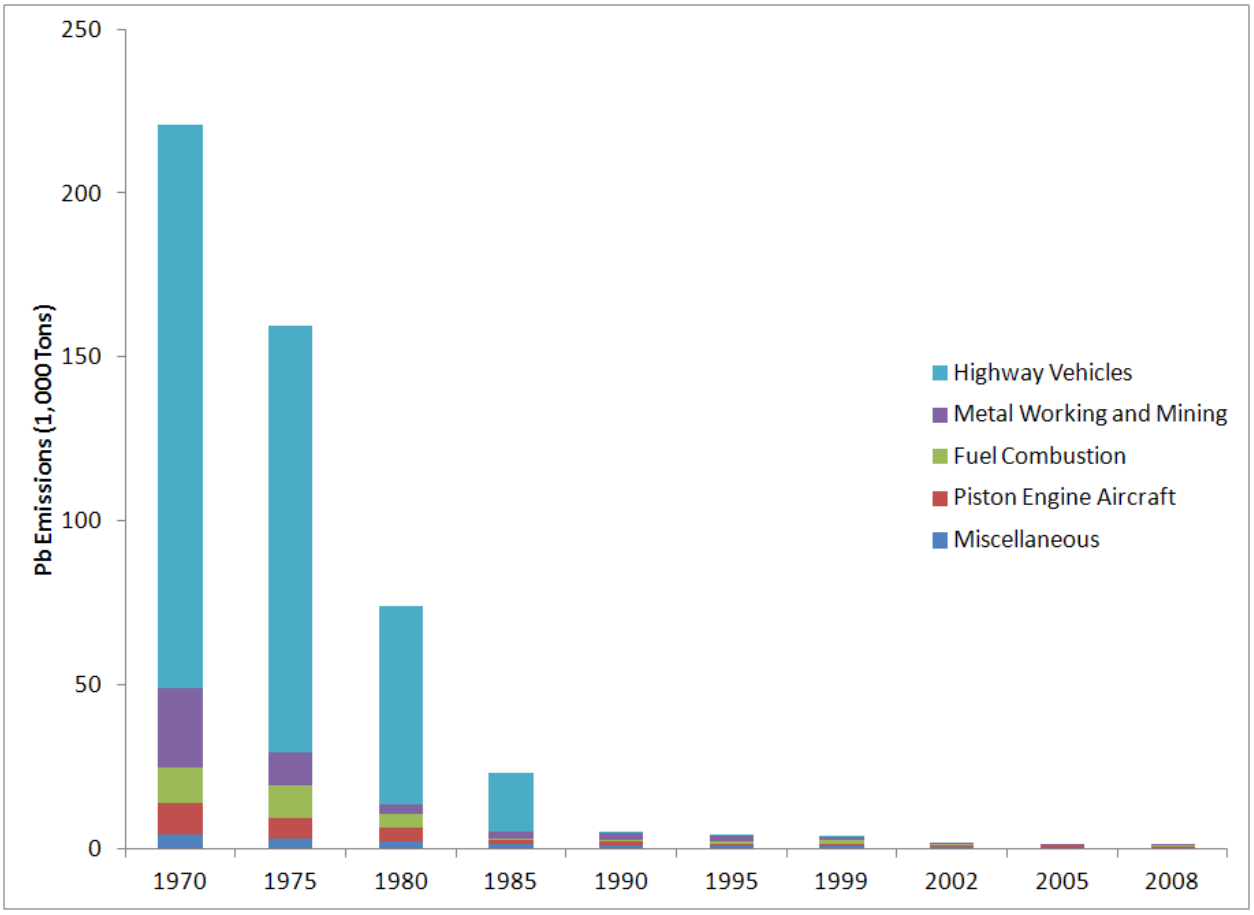
3.2.1 National Emissions Inventory

The 2006 Pb AQCD (U.S. EPA, 2006b) listed the largest sources to be (in order): industrial-commercial-institutional boilers and process heaters (17%), coal utilities boilers (12%), mobile sources (10%), iron and steel foundries (8%), and miscellaneous sources from industrial processes, incineration, and utilities, each contributing less than 5% (53%). The sources listed in the 2006 Pb AQCD were based on the 2002 NEI (U.S. EPA, 2006a). Subsequent correction of computational errors prior to completion of the 2008 NAAQS review provided corrected estimates for the 2002 inventory which indicated the largest sources to be (in order): mobile sources from leaded aviation gas usage in piston-engine aircraft (45%), metallurgical industries (23%), manufacturing (14%), incineration (8%), boilers (6%), and miscellaneous sources contributing less than 5% (U.S. EPA, 2007h). The 2002 and prior year inventories discussed in this document reflect the corrected information.

Emissions of Pb have dropped substantially over the past forty years, as shown in Figure 3-1 and Figure 3-2. The reduction before 1990 is largely due to the phase-out of Pb as an anti-knock agent in gasoline for on-road automobiles, as discussed in the 2006 Pb AQCD (U.S. EPA, 2006b). This action resulted in a 98% reduction in Pb emissions from 1970-1995. Total Pb emissions over the period 1995-2008 decreased an additional 76%, from 4,100 tons in 1995 to 964 tons in 2008. Additional emissions reductions are related to enhanced control of the metals processing industry. In 1995, metals processing accounted for 42% (2,200 tons) of total Pb emissions. By 2008, metals processing accounted for 17% (168 tons) of total emissions. This represented more than an order of magnitude decrease in Pb emissions from metals processing. Emissions from piston-engine aircraft decreased 34% over this time period. In 1990, nonroad Pb emissions were 990 tons, 830 tons of which were generated from piston-engine aircraft, and represented 19% of total Pb emissions. In 2008, nonroad Pb emissions from piston-engine aircraft were slightly lower at 550 tons,[1] which represented 57% of all Pb emissions. 2008 piston-engine aircraft emissions were comprised of 254 tons of Pb from emissions at or near airports and 296 tons of Pb emitted in flight (i.e., outside the landing and take-off cycles). "Miscellaneous" emissions from other industrial processes, solvent utilization,

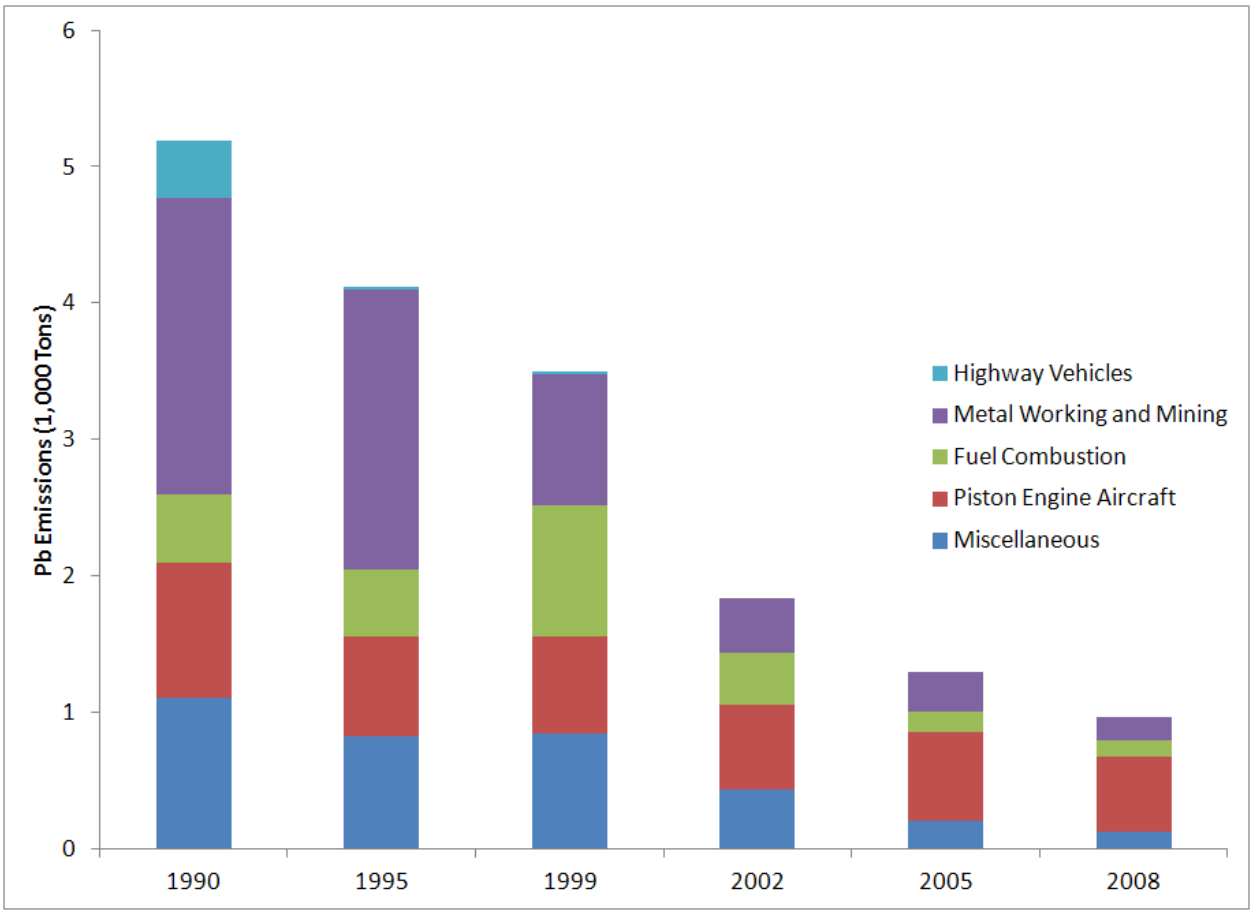
[1] This reflects EPA's best estimates of piston-engine aircraft emissions. The piston-engine aircraft emissions inventory can be obtained from the following site: http://www.epa.gov/ttn/chief/net/2008neiv2/2008_neiv2_tsd_draft.pdf.

agriculture, and construction constituted 3% of emissions (25 tons) in 2008 (U.S. EPA, 2011a, 2008a).



Source: U.S. EPA (2011a, 2008a)

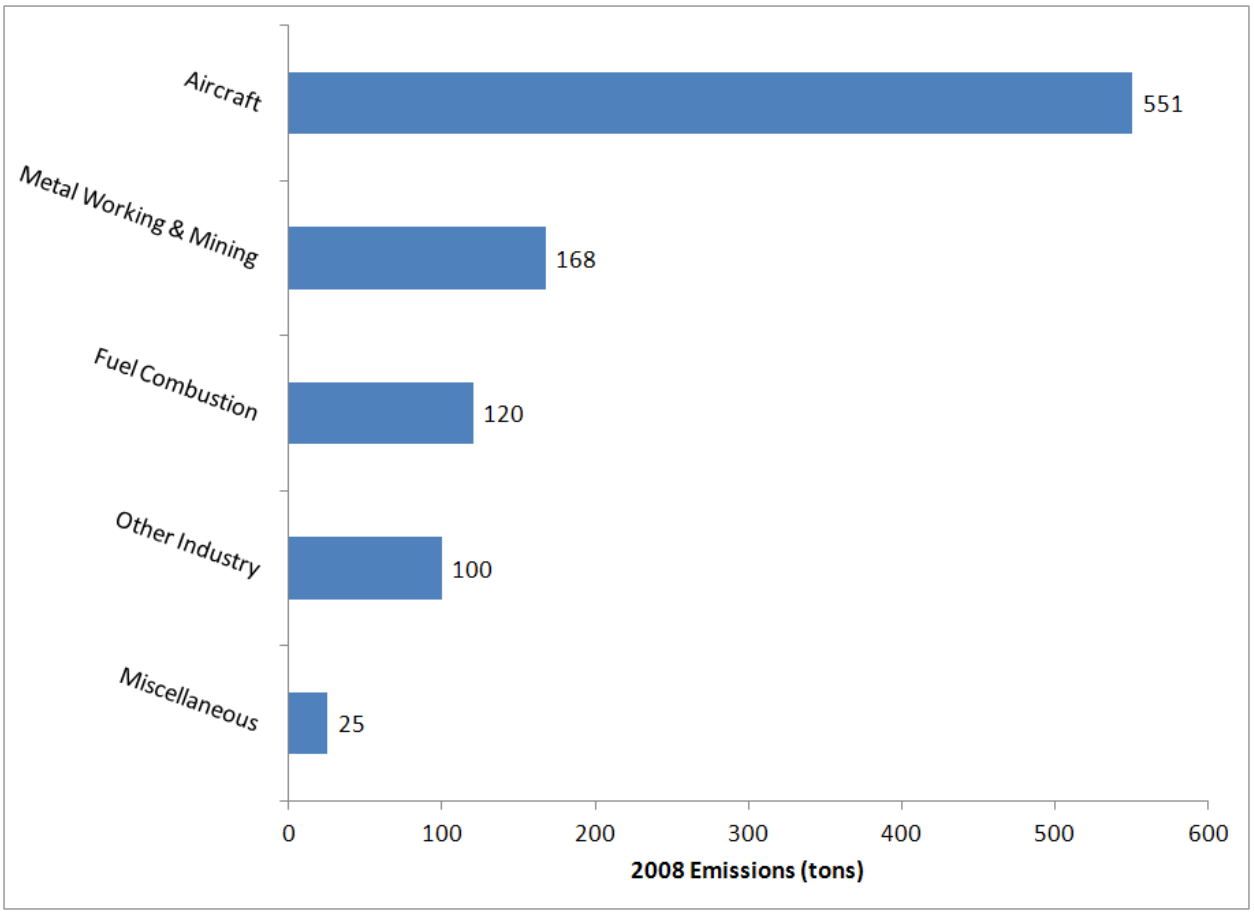
Figure 3-1 Trends in Pb emissions (thousand tons) from stationary and mobile sources in the U.S., 1970-2008.



Source: U.S. EPA (2011a, 2008a)

Figure 3-2 Trends in Pb emissions (thousand tons) from stationary and mobile sources in the U.S., 1990-2008.

Direct emissions of Pb into the atmosphere primarily come from piston-engine aircraft, fuel combustion, and industrial activities. Direct Pb emissions estimated by the 2008 NEI are shown in Figure 3-3. Piston-engine aircraft produced 57% of all emissions (550 tons). Metal working and mining contributed 168 tons (17%) of Pb emissions in 2008, followed by fuel combustion (12%), other industry (10%), and miscellaneous contributions from agriculture, solvent utilization, and operation of commercial marine vessels and locomotives (3%) (U.S. EPA, 2011a). Pb emissions from the "metal working and mining" category include the single primary Pb smelter in the U.S., the Doe Run facility in Herculaneum, MO; secondary Pb smelters, mostly designed to reclaim Pb for use in Pb-acid batteries; and smelters for other metals.

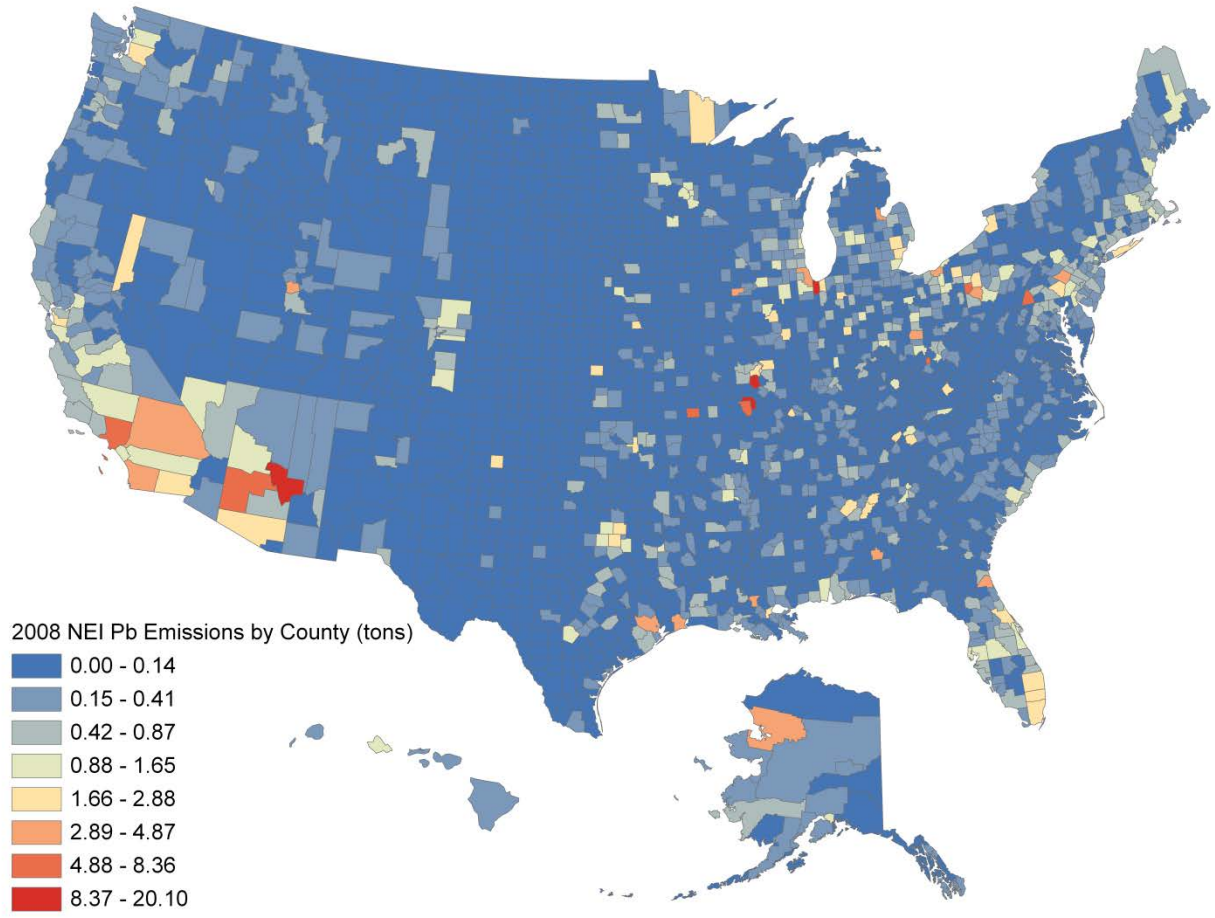


Source: U.S. EPA (2011a)

Figure 3-3 Nationwide stationary and mobile source Pb emissions (tons) in the U.S. by source sector in 2008.

There is substantial variability in Pb emissions across U.S. counties, as shown in Figure 3-4 for the continental U.S. The emissions levels, shown in units of tons, vary over several orders of magnitude. Ninety-five percent of U.S. counties, territories, and tribal areas had 2008 emissions below 1 ton; 50% of counties, territories, and tribal areas had 2008 emissions below 0.041 tons. Jefferson County, MO was the highest emitting single county, with over 20 tons of airborne Pb emissions in 2008. Jefferson County is home to the Doe Run primary Pb smelting facility, which is the only remaining operational primary Pb smelter in the U.S. and is planning to cease the existing smelter operations at this site by April, 2014 (DRRC, 2010). Pb emissions from piston-engine aircraft operating on leaded fuel are estimated to occur at approximately 20,000 airports across the U.S. Many of the more active airports are more numerous in highly populated metropolitan regions, which suggests that emissions from piston-engine aircraft may be higher in these locations compared with rural areas. In twenty-five counties, piston-

engine aircraft are estimated to emit cumulatively greater than one ton of Pb in 2008 U.S. EPA (2011a).



Source: U.S. EPA (2011a)

Figure 3-4 County-level Pb emissions (tons) in the U.S. in 2008.

Figure 3-5 illustrates the locations and relative magnitude of Pb emissions for 182 facilities in the U.S. emitting 0.5 tons or more in 2008 (U.S. EPA, 2011a). One facility, Doe Run in Herculaneum (Jefferson Co.), MO, emitted more than 10 tons in 2008. Additionally, the map illustrates several locations where there is a confluence of point sources (not to be confused with total sources including non-point), including Jefferson Co., MO, Lake Co., IN, Iron Co., MO, and Gila, AZ, in each of which are facilities that were estimated to cumulatively emit more than 10 tons. Among the facilities shown, 124 are non-airport facilities; nine of these were estimated to emit more than 5 tons, 52 to emit between 1 and 5 tons, and 63 to emit between 0.5 and 1 tons in 2008. Figure 3-5

additionally includes 58 airports, the six largest of which were estimated to emit between 1 and 1.3 tons.

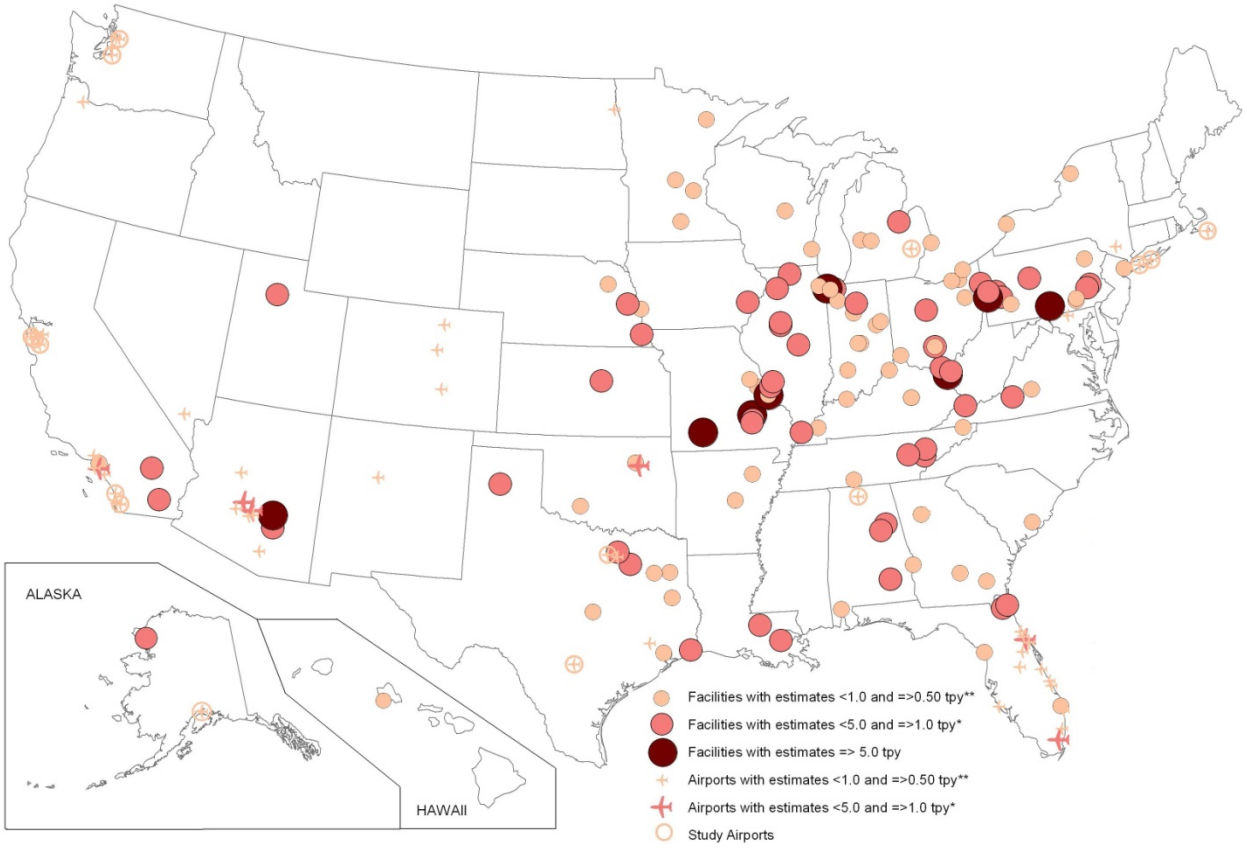


Figure 3-5 Pb facilities estimated to emit 0.5 tons or more in 2008.

3.2.2 Anthropogenic Sources

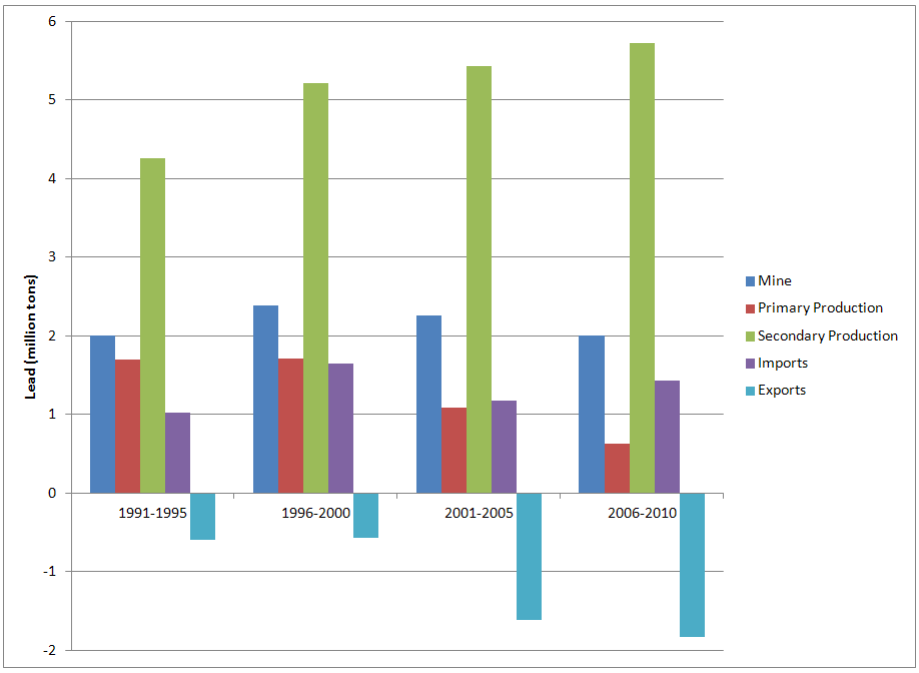
Anthropogenic Pb source categories are organized below in order of magnitude with regard to the sum of emissions nationally reported on the 2008 NEI (U.S. EPA, 2011a). Pb sources were reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) by species. Forms of Pb commonly observed in the environment are carried forward from the 2006 Pb AQCD (U.S. EPA, 2006b) and are presented in Table 3-1 to serve as a reference for the categories of Pb sources described in Sections 3.2.1 and 3.2.2.

Table 3-1 Pb compounds observed in the environment.

Emission Source	Observed Pb Compounds
Minerals	PbS (Galena)
	PbO (Litharge, Massicot)
	Pb_3O_4 (“Red Pb”)
	$PbSO_4$ (Anglesite)
Smelting aerosols	Pb^0, PbS
	$PbSO_4$, PbO
	$PbCO_3$
	Pb silicates
Coal combustion aerosols	PbS
	PbSe
Coal combustion flue gases	Pb^0, PbO, PbO_2 (Above 1,150 K)
	$PbCl_2$ (Low rank coals, above 1,150 K)
	$PbSO_4$ (Below 1,150 K)
Wood combustion	$PbCO_3$
Waste incineration aerosols	$PbCl_2$, PbO
Soils near mining operations	$PbCO_3$
	$PbSO_4$
	$[PbFe_6(SO_4)_4(OH)_{12}]$
	$[Pb_5(PO_4)_3Cl]$
	$[Pb_4SO_4(CO_3)_2(OH)_3]$
	$PbS\text{-}Bi_2S_3$
	Pb oxides, silicates
Piston-engine aircraft emissions, racing vehicle exhaust (combustion of leaded fuel)	$PbBr_2$
	Alkyl Pb
	$PbBrCl\text{-}NH_4Cl$, $PbBrCl\text{-}2NH_4Cl$
Roadside dust	$PbSO_4$, Pb^0, $PbSO_4(NH_4)SO_4$, Pb_3O_4, $PbO\text{-}PbSO_4$ and $_2PbCO_3\text{-}Pb(OH)_2$
Brake wear, wheel weights	Pb^0
Aircraft engine wear	Pb^0

Source: Biggins and Harrison (1980, 1979); U.S. EPA (2006b).

Pb emissions in the U.S. derive from a combination of mined, processed, and imported Pb. Figure 3-6 illustrates trends in the origin of Pb used in the various sectors described below over the period 1991-2010. Over this time period, the amount of Pb used in secondary Pb processing increased by 37%, while exports of Pb increased by 103%. Primary Pb processing decreased by 67%. Pb mining and imports fluctuated over 1991-2010 without a clear increasing or decreasing trend. In 2008, 1.28 million tons of Pb were introduced to the market by primary and secondary processing combined. 964 tons of Pb were emitted to the ambient air. Hence, 99.9% of Pb produced in 2008 remained in products or was emitted directly to soil or water following disposal.



Note: Exports are shown by negative numbers to illustrate that the Pb was leaving the U.S. Data were aggregated into five-year totals to stabilize the data shown.

Source: U.S. Geological Survey (2012, 2006; 2001; 1996)

Figure 3-6 Five-year totals for Pb mining, primary and secondary production, imports, and exports, 1991-2010.

3.2.2.1 Pb Emissions from Piston-engine Aircraft Operating on Leaded-Aviation Gasoline and Other Non-road Sources

The largest source of Pb in the NEI, in terms of total emissions nationally, is emissions from piston-engine aircraft operating on leaded aviation gasoline (U.S. EPA, 2011a). As outlined in Table 3-1, there are several forms of Pb emitted from engines operating on leaded fuel. Dynamometer testing has indicated that Pb emissions from piston engines operating on leaded fuel can occur in the particulate and gaseous forms. For example, Gidney et al. (2010) performed dynamometer testing on automobiles operating on standard gasoline and on gasoline with low levels of organometallic additives. Tetraethyl Pb was included since it is still used in piston-engine aircraft fuel. Gidney et al. (2010) point out that, where tetraethyl Pb is used as an additive in piston-engine aircraft fuel, the fuel also contains ethylene dibromide, which reacts with Pb to form Pb bromide and Pb oxybromides. Pb bromides and Pb oxybromides are more volatile than elemental Pb at combustion temperatures and are therefore exhausted from the engine. After being exhausted, the brominated Pb compounds cool to ambient temperatures and condense to form solid particles. In contrast, emissions of organic Pb would remain largely in the vapor phase at ambient temperatures. Studies of Pb emissions within enclosed microenvironments where automobiles were the dominant Pb source cited within the 1986 Pb AQCD (U.S. EPA, 1986a), reported that organic Pb vapors contributed less than 20% of total vehicular Pb emissions. A more recent study supports this (Shotyk et al., 2002). The 20% estimate of organic Pb emissions from the previous studies of on-road Pb emissions may potentially provide an upper bound for organic Pb emissions from current piston-engine aircraft.

Pb emission rates from piston aircraft vary with fuel consumption rates, which depend on the engine/airframe combination and the mode of operation of the aircraft. The ASTM specification for the maximum Pb content in “100 Low Lead”, the most commonly used leaded piston-engine aircraft fuel, is 2.12 g of elemental Pb/gallon (ASTM, 2007). Fuel consumption rates can be obtained for some engine/aircraft combinations by running FAA’s Emissions and Dispersion Modeling System (FAA, 2011). Fuel consumption for piston-engine aircraft operating at one airport in the U.S. were estimated to range from 1.6 g/sec of fuel during taxi-out to 15.3 g/sec of fuel during run-up preflight check for single-engine aircraft and 5.1 g/sec during taxi and 50 g/sec during preflight run-up check for twin-engine aircraft (Carr et al., 2011). Fuel consumption rates for aircraft listed in FAA’s Emissions and Dispersion Modeling System were used to develop the Pb emissions inventory for piston aircraft that are discussed in Section 3.2.1. EPA estimates that on average, 7.34 g of Pb is emitted during a landing and take-off cycle conducted by piston-engine aircraft (ERG, 2011).

3.2.2.2 Emissions from Metals Processing and Mining

High Pb emissions were observed in the 2008 NEI (U.S. EPA, 2011a) in Herculaneum, MO, where the Doe Run Pb smelter is operated. Although it is set to cease smelting operations in 2014 (DRRC, 2010), it is of interest to consider studies of primary smelter emissions in the context of the data analyzed in this ISA. Batonneau et al. (2004) and Sobanska et al. (1999) found that the Pb content in PM emitted from a primary Pb smelter was 56.6% by weight, and the Pb content in PM from a Pb/Zn smelter was 19.0% by weight. Choel et al. (2006) confirmed that Pb was strongly associated with sulfur in Pb-Zn smelter emission PM, and that Pb sulfates and Pb oxy-sulfates were the most abundant species, with important contributions from Pb oxides. Pb concentrations 1,800 meters downwind of the smelter (0.625-0.880 $\mu g/m^3$) were roughly thirty-five times higher than a monitor 1,800 meters upwind (0.017-0.026 $\mu g/m^3$).

Fugitive emissions (i.e., unaccounted ambient air Pb emissions) from secondary Pb processing (e.g., Pb recovery from batteries) can be substantial over the course of a year, but they are difficult to estimate. Thurston et al. (2011) performed source apportionment of $PM_{2.5}$ found that Pb-$PM_{2.5}$ concentrations from the Chemical Speciation Network (CSN) were associated with the metals industry along with Zn-$PM_{2.5}$. Goyal et al. (2005) estimated fugitive emissions using concentration data obtained from samplers sited in close vicinity of secondary Pb processing facilities and meteorological data from nearby weather monitoring stations. Regression modeling and Bayesian hierarchical modeling were both used to estimate fugitive and stack emissions from secondary Pb processing facilities in Florida, Texas, and New York. Depending on the model used, median fugitive emissions were estimated to be 1.0×10^{-6} to 4.4×10^{-5} g Pb/m^2·sec at the Florida site, 9.4×10^{-7} to 2.0×10^{-6} g/m^2·sec for the Texas site, and 8.8×10^{-7} to 1.1×10^{-6} g/m^2·sec at the New York site. Median stack emissions estimates varied widely among the models, with the Florida site median ranging from 1.4×10^{-6} to 1.4×10^{-1} g Pb/sec, the Texas site median ranging from 8.4×10^{-2} to 8.6×10^{-2} g/sec, and the New York site ranging from 8.4×10^{-3} to 1.0×10^{-2} g/sec. Additionally, the Bayesian hierarchical model was used to estimate fugitive Pb emissions from secondary Pb processing facilities nationwide using concentration data as prior information. Nationwide median fugitive emissions from secondary Pb processing facilities were estimated to be 9.4×10^{-7} to 3.3×10^{-6} g/m^2·sec. Recently, speciation of emissions from a battery recycling facility indicated that PbS was most abundant, followed by Pb sulfates ($PbSO_4$ and $PbSO_4$-PbO), PbO and Pb^0 (Uzu et al., 2009).

In addition to secondary Pb smelting, Pb emissions occur from processing of other metals. For example, a recent study examined Pb emissions from a sintering plant, a major component of the steel making process in southern France (Sammut et al., 2010).

Cerussite, a Pb carbonate ($PbCO_3$-$2H_2O$), was observed to be the most abundant species and contributed 20 g Pb/kg measured PM. In another example, Reinard et al. (2007) used a real-time single particle mass spectrometer to characterize the composition of PM_1 collected in Wilmington, Delaware in 2005 and 2006. Strong Pb-Zn-K-Na associations were observed within 13% of PM samples. Comparison with stack emissions revealed that a nearby steel manufacturing facility was an important source of Pb. Ambient PM classes containing only a subset of such elements, e.g., Zn only, Pb-K only were non-specific and so could not be mapped to individual sources. Ogulei et al. (2006) observed that 6% of Pb in $PM_{2.5}$, along with some O_3, Cu, and Fe, was attributed to steel processing in Baltimore, MD. Murphy et al. (2007) conducted a detailed study of the distribution of Pb in single atmospheric particles during the fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere campaign at the Jungfraujoch High Altitude Research Station in Switzerland and found that the predominant type of urban Pb-bearing aerosols contained Pb together with K and Zn. The mode of the size distribution for this type was around 200 nm.

Waste from current or defunct mines has been shown to present an additional fugitive source of Pb. For example, distribution of Pb along a haul road connecting an active mine to a port has been documented in Alaska (see Section 3.6.6). Additionally, Zheng et al. (2009) applied source apportionment in three northeastern Oklahoma towns to identify the influence of "chat", or waste piles from formerly operational Pb-Zn mines, on $PM_{10\text{-}2.5}$ and $PM_{2.5}$. They estimated that mine waste was responsible for 88% of Pb in $PM_{10\text{-}2.5}$ samples and 40% of Pb in $PM_{2.5}$ samples.

3.2.2.3 Fossil Fuel Combustion

Murphy et al. (2007) found that the volatility of Pb and its compounds such as PbO may result in its presence at high concentration in the submicron fraction of PM emitted from coal emissions. $PbSO_4$, also derived from coal combustion, has low water solubility (Barrett et al., 2010). $PbSO_4$ was estimated to comprise 37% of Pb in PM_{10} from a 2002-2003 study of PM in Shanghai, China (Tan et al., 2006) and 0.6% of total PM_{10} from a study of PM in Taiyuan City, China (Xie et al., 2009). Murphy et al. (2007) presented an estimated U.S. mass budget for Pb emitted from consumption of select fuels and crude oil. Fuel consumption estimates for 2005 were employed (Freme, 2004). Based on an annual consumption of 1.0×10^9 metric tons coal with an average Pb concentration of 20 mg/kg (range: 5 to 35 mg/kg) and using an emission factor (airborne fraction) of approximately 0.01, coal contributed approximately 200 metric tons Pb/yr to the atmosphere. At the time of the Murphy et al. (2007) study, there were no emission factors available to estimate airborne Pb emissions for crude oil or residual oil, but these

represent potentially large sources (with total Pb in these sources estimated by Murphy et al. (2007) to be as much as 100-500 metric tons/year and 25-700 metric tons/year, respectively). These calculations imply that there is substantial uncertainty in estimates of Pb emissions resulting from fuel combustion. It is important to note that Murphy et al. (2007) state that the crude oil estimates are based on a limited number of samples and that there was uncertainty in the estimates of Pb content in residual oil. Furthermore, Murphy et al. (2007) was based on data ranging back in time from 1972 to 2005. Therefore, the Murphy et al. (2007) findings do not necessarily conflict with reported ambient air Pb emissions from the NEI. As part of recent rulemaking, EPA has developed a draft Pb emission factor of $1.3x10^{-5}$ lb/MMBtu for boilers larger than 25 MW that use #2 or #6 fuel oil (U.S. EPA, 2011b).The amounts of Pb emitted from these U.S. sources, however, are several orders magnitude smaller than those estimated to arise from coal combustion in China.

Coal combustion is considered to be a major source of Pb in the atmosphere now that leaded gasoline has been phased out for use in on-road vehicles (Diaz-Somoano et al., 2009). Global Pb estimates are considered here to inform understanding of U.S. Pb emissions from coal combustion. McConnell and Edwards (2008) examined correlations of Pb with BC, Cd, Ce, sea salt Na, non-sea salt S, and Tl in a Greenland ice core and observed high correlations for BC, Cd, non-sea salt S and Tl during the period 1860-1940, when coal combustion was the predominant energy source. With the exceptions of non-sea salt S and Tl, the high correlations were not maintained into the years 1940-2003, when oil combustion was the most prevalent energy source. This suggests common industrial sources of PbS or $PbSO_4$. Rauch and Pacyna (2009) constructed global metal cycles using anthropogenic data from 2000. They confirmed that the largest anthropogenic airborne Pb emissions arise from fossil fuel combustion, and they quantified Pb emissions at 85,000 tons/year worldwide. Globally, Pb emissions from stationary sources have been increasing and the north-south gradient in aerosol Pb concentrations over the Atlantic Ocean has disappeared as a result of industrialization of the southern hemisphere (Witt et al., 2006; Pacyna and Pacyna, 2001). The Pb isotope ratio values (mainly $^{206}Pb/^{207}Pb$) for coal from around the world have been compared with those for atmospheric aerosols. In most parts of the world, there has been a difference between the signature for aerosols and that for coal, where the atmospheric $^{206}Pb/^{207}Pb$ ratio values are lower, indicative of additional contributions from other sources. Zhang et al. (2009a) used single particle aerosol mass spectrometry (ATOFMS) to find that PM containing Pb along with OC and/or EC was attributed to coal combustion processes in Shanghai, China; this accounted for roughly 45% of Pb-bearing PM.

Seasonal effects of the contributions of Pb emissions from coal combustion have been observed. For example, in Tianjin, northern China, the winter heating period starts in

November, and the contribution from coal combustion to the Pb aerosol becomes high during the winter. This leads to both a high Pb content and a high $^{206}Pb/^{207}Pb$ ratio. Coal consumption and Pb-bearing PM concentrations declined during the summer months, and Pb from other sources, mainly vehicle exhaust emissions, became relatively more pronounced (Wang et al., 2006c). This seasonal relationship contrasts with observations for the U.S. when power stations are more active in summer months (EIA, 2012). The increased energy use in summer periods in the U.S. may be attributable to increased requirements for air-conditioning.

3.2.2.4 Waste Incineration

Waste incineration studies suggest that the Pb content vary by industrial or municipal waste stream. For example, Ogulei et al. (2006) performed positive matrix factorization of $PM_{2.5}$ and gaseous copollutants for Baltimore, MD and observed that 63% of Pb in $PM_{2.5}$ was attributed to waste incineration during the six day study duration. Other prevalent compounds associated with incineration included NO_3^-, EC, Cd, Cu, Fe, Mn, Se, Zn, O_3, and NO_2 (note that Cl was not observed in this study). Likewise, Song et al. (2001) used PMF to deduce sources of $PM_{2.5}$ measured at Washington, D.C., Brigantine, NJ, and Underhill, VT during the years 1988-1999. They observed a waste incineration source loaded with OC, EC, Pb, and Zn at all three sites. A study by Moffet et al. (2008b) found that Pb-Zn-Cl-containing particles in $PM_{2.5}$ samples collected from an industrial area in Mexico City represented as much as 73% of fine PM. These were mainly in the submicron size range and were typically mixed with elemental carbon (EC), suggesting a combustion source. Zhang et al. (2009a) also observed high correlation between Pb and Cl associated with waste incineration in Shanghai, China. Several Pb isotope studies have also been used to distinguish contributions to incineration from industrial sources. Isotope analysis is discussed in more detail in Section 3.4.1.5. Novak et al. (2008) evaluated changes in the amounts and sources of Pb emissions in the U.K. and Czech Republic during the 19th and 20th centuries and found uncertainty in the amount and the isotope composition of Pb emanating from incineration plants. The isotopic signature of Pb recycled into the atmosphere by incineration of various industrial wastes could have shifted from relatively high $^{206}Pb/^{207}Pb$ ratios consistent with local Variscan ores to lower values reflecting imported Precambrian ores. However, other environmental studies concerning incineration have given highly consistent values for the Pb isotope ratio for European incineration sources. For example, Cloquet et al. (2006) showed that the Pb isotopic composition of urban waste incineration flue gases in northeastern France was ~1.16. De la Cruz et al. (2009) reported that waste incineration was an important source of Pb and showed that the $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}$ Pb ratios for waste incineration Pb

emitted in European countries were 1.14-1.16 and 2.43 respectively (de la Cruz et al., 2009).

3.2.2.5 Wood Burning

Another potentially uncontrollable source is Pb deposited historically in forests and remobilized during forest fires. Section 4.1.3.1 describes residential Pb-PM concentrations related to in-home burning of wood contaminated with Pb of ambient origin, while this section describes ambient air measurements of Pb attributed to wood burning. The 2006 Pb AQCD (U.S. EPA, 2006b) presented data by Nriagu (1989) estimating that 1,900 metric tons of Pb were emitted globally each year from wildfires. Wildfire Pb emissions were not included in the NEI. Murphy et al. (2007) observed that a fraction of particles contained small quantities of Pb on biomass particles measured using ATOFMS to sample directly from forest fire plumes in northwest Canada and eastern Alaska in July, 2004; these particles also typically contained SO_4^{-2}. Several studies illustrate moderate-to-long range transport of biomass burning plumes containing Pb. Using positive matrix factorization, Ogulei et al. (2006) estimated that 20% of Pb in $PM_{2.5}$ measured in Baltimore, MD was attributed to a July, 2002 episode of wildfires in Quebec, Canada in his 6-day study. Other components strongly associated with the Quebec wildfires included NO_3^-, OC, EC, Cd, Mn, Zn, O_3, and CO. Qureshi et al. (2006) also observed a spike up to 42 ng/m^3 in Pb-$PM_{2.5}$ concentration in Queens, NY coinciding with the Quebec wildfires; for comparison, the authors provide the 3-month average from July to September of 5.1 ng/m^3 for Pb-$PM_{2.5}$ in Queens. Similarly, Anttilla et al. (2008) measured PM_{10} in Virolahti, Finland during a wildfire in Russia and observed average Pb-PM_{10} concentrations during the forest fire episodes to be 1.7-3.0 times higher than the reference concentration of 3.5 ng/m^3. Hsu et al. (2009c) observed Pb concentrations in Taiwan attributed to biomass burning in Northeastern China; Pb was highly correlated with K attributed to biomass burning during these episodes. Odigie and Flegal (2011) studied remobilization of Pb during the 2009 wildfires in Santa Barbara, CA. Pb concentrations in ash samples obtained after the wildfire ranged from 4.3 to 51 mg/kg. Isotopic analysis of the ash suggested that the remobilized Pb was initially emitted by a mix of contemporary and previous industrial sources and historic combustion of leaded gasoline. Grouped with “miscellaneous” Pb emissions, fires from agricultural field burning and prescribed fires accounted for 2.4 tons of U.S. Pb emissions in 2008 (U.S. EPA, 2011a). Polissar et al. (1998) used positive matrix factorization to apportion $PM_{2.5}$ and found small Pb signals attributed to the forest fire factor at two of six Alaskan sites where a forest fire factor was detected; the forest fire factor was dominated by a combination of BC, H^+, and K.

Several studies have explored the chemical properties of biomass emissions. Obernberger et al. (2006) simulated biomass combustion in a laboratory setting to assess emissions. They reported pre-combustion mean Pb content in wood, bark, and logging residues to range from 2-5 mg/kg dry basis. They reported volatilization and subsequent condensation of Pb emissions from combustion. Van Lith et al. (2008; 2006) studied the inorganic element content of wood chips and particle board and the release of inorganic elements during combustion of those materials in laboratory experiments. They measured a Pb content of 16 mg/kg dry basis in particle board and of 0.44 mg/kg dry basis in spruce wood chips. Using three different types of combustion for different materials, they found that up to 10% of Pb was released at a combustion temperature of 500 °C and up to 85% was released at a temperature of 850 °C. At temperatures greater than 650 °C, PbO gas was released under oxidizing conditions; under reducing conditions, Pb gas, PbCl gas, and PbS gases were released at temperatures above 500 °C. Jimenez et al. (2008) performed laboratory experiments of olive tree combustion and concluded that Pb vaporizes upon combustion and then condenses between 900 °C and 560 °C. Jimenez et al. (2008) also observed that Pb concentration in PM changes with oxygen content and temperature, with concentrations converging toward 2,000 mg/kg for increasing percent available oxygen and increasing temperature.

Pb deposition on trees has been documented in Acadia National Park in Maine with mean foliar concentrations ranging from <0.5 to 3.1 mg/kg (Wiersma et al., 2007). Tree ring core samples obtained in the Czech Republic illustrate that the amount of Pb deposited on trees from coal and leaded gasoline combustion sources tended to increase over the depth of the core, with maximum concentrations corresponding to time periods of 1969-1972, 1957-1960, and 1963-1966 in three samples (Zuna et al., 2011).

3.2.2.6 Roadway-Related Sources

Contemporary Emissions from Vehicle Parts

Contemporary Pb emissions from motor vehicles may occur because several vehicle parts still contain Pb. Wheel weights, used to balance tires, are clipped to the rims of tire wheels in order to balance the tires, and may become loose and fall off. Pb wheel weights have been banned in several states including Washington, Maine, and Vermont with legislation considered in Iowa, California, and Maryland. However, Pb wheel weights are a source in most states for the period of time covered in this assessment. Ambient air Pb concentrations near heavily trafficked areas may be related to use of Pb-based wheel weights that are prone to dislodgement. Root (2000) and Aucott and Caldarelli (2012) estimated that 2.7-5% of the mass of wheel weights is deposited from cars to the road

daily. Aucott and Caldarelli (2012) extrapolated their results for Mercer County, NJ to the U.S. to estimate that 480 tons of Pb are deposited to roadways each year. On pavement they may be ground into dust by the pounding forces of traffic (Root, 2000). For example, Aucott and Caldarelli (2012) estimated that 13.8 ± 5.0% of the deposited mass of wheel weights are dispersed each year through abrasion and grinding by traffic. Schauer et al. (2006) measured Pb emissions in two traffic tunnels and found that the Pb-$PM_{2.5}$ concentration did not exceed 17% of the Pb-PM_{10} concentration in any of the runs. Schauer et al. (2006) suggested that enrichment in the coarse fraction may have been related to wheel weights. Additionally, Schauer et al. (2006) measured PM_{10} and $PM_{2.5}$ composition from brake dust and found concentrations that were low but statistically significantly greater than zero for Pb in PM_{10} (0.02 ± 0.01 mg/g) and Pb in $PM_{2.5}$ (0.01 ± 0.00 mg/g) for semi-metallic brake pads and for Pb in PM_{10} (0.01 ± 0.00 mg/g) for low-metallic brake pads. Song and Gao (2011) speciated coarse and fine PM samples obtained next to the New Jersey Turnpike in winter and summer of 2007-2008. Using principal component analysis, they found that Pb was prevalent in the factor including automobile exhaust and brake wear. Pb was observed to have a similar size distribution as Zn in the winter and Zn and Cd in the summer, with higher concentrations in the fine fraction at a mode of 0.18-0.32 µm. Fauser (1999) observed that 90% of particles generated by tire abrasion are smaller than 1 µm. Similarly, Maher et al. (2008) observed that vehicle-derived Pb was observed with fine particles smaller than 1 µm; however, they concluded based on the submicrometer size of the particles that fuel combustion, not tire wear, was the primary source of Pb. Additionally, Hjortenkrans et al. (2007) used material metal concentrations, traffic volume, emissions factors, and sales data to estimate the quantity of Pb emitted from brake wear and tires in Stockholm, Sweden in 2005. They observed that 24 kg (0.026 ton) of Pb were emitted from brake wear each year, compared with 2.6 kg (0.0029 ton) of Pb from tire tread wear; an estimated 549 kg (0.61 ton) was estimated to have been emitted from brake wear in 1998. McKenzie et al. (2009) determined the composition of various vehicle components including tires and brakes and found that tires were a possible source of Pb in stormwater, but no identification of Pb-containing PM in stormwater was carried out. However, PM from tire abrasion is usually found in coarser size ranges (Chon et al., 2010), while those in the submicron range are more typically associated with combustion and incineration sources.

Unleaded Fuel

Unleaded fuel contains Pb as an impurity within crude oil (Pacyna et al., 2007). Schauer et al. (2006) measured Pb in $PM_{2.5}$ from tailpipe emissions and observed quantities in on-road gasoline emissions that were statistically significantly different from zero

(83.5 ± 12.80 mg/kg), whereas emissions of Pb from diesel engines were not statistically significantly different from zero. Hu et al. (2009a) investigated the heavy metal content of diesel fuel and lubricating oil. They found <1-3 mg/kg Pb in samples of lubricating oil. Hu et al. (2009a) also measured the size distribution of Pb emissions during dynamometer testing of heavy duty diesel vehicles with different driving patterns and control technologies. An urban dynamometer driving schedule (UDDS) designed to mimic urban stop-go driving conditions, was simulated in two cases to produce 80 and 241 ng Pb/km driven, depending on the control technology used. Respectively, 54% and 33% of those emissions were smaller than 0.25 μm in mass median aerodynamic diameter (MMAD). Song et al. (2001) and Polissar et al. (2001) both used positive matrix factorization to decompose $PM_{2.5}$ samples obtained from an Underhill, VT site [Song et al. (2001) used data from 1988-1999 and Polissar et al. (2001) used data from 1988-1995] and observed a "Canadian Mn" factor loaded with Mn and Pb. Methylcyclopentadienyl manganese tricarbonyl had been used in Canada as an antiknock agent to replace tetraethyl and tetramethyl Pb additives, but it is not clear if the co-occurrence of Mn with Pb denotes that the phase-out had not been completed during part of the study period (Canadian phase-out completed in 1993).

3.2.2.7 Deposited Pb

Soil Pb can serve as a reservoir for deposited Pb. The following subsections describe studies of previously deposited Pb that originated from industrial activities, historical use of leaded on-road gasoline, and urban sources such as paint and building materials. The 2006 Pb AQCD (U.S. EPA, 2006b) cited an estimate by Harris and Davidson (2005) that more than 90% of airborne Pb emissions in the South Coast Basin of California were from soil resuspension. This value was obtained by constructing mass balances rather than from direct measurements of Pb along roads, and hence it is an estimate. Currently, measured data are not available with sufficient spatial resolution to discern the specific contribution of soil Pb resuspension to air Pb concentration, but resuspended soil Pb cannot be eliminated as a potential source of airborne Pb. Section 3.5.1.2 includes recent information on ambient air concentrations of Pb-TSP, sampled at 6 meters above ground level (AGL), at a distance of 500 meters from the heavily trafficked Interstate I-405, and 10 meters from a busy arterial road in Los Angeles. From this monitor, average concentrations were not substantially higher than the local urban background concentration (Sabin et al., 2006b). Insufficient data are available to ascertain if the near road Pb-TSP concentrations would be higher at lower monitor heights. The 2006 Pb AQCD (U.S. EPA, 2006b) also noted a smaller estimate of 40% for the Southern California Air Basin (Lankey et al., 1998).

In a recent paper, Laidlaw and Filipelli (2008) analyzed Interagency Monitoring of Protected Visual Environments (IMPROVE) data to explore conditions under which $PM_{2.5}$ particles estimated to be of crustal origins that may contain Pb may become airborne. They observed a seasonal pattern in the concentration of $PM_{2.5}$ of crustal origins in the atmosphere, and they also found that at one IMPROVE site in central Illinois, 83% of the variability in concentrations of crustal $PM_{2.5}$ was predicted by variability in meteorology and soil moisture content. The authors concluded that seasonality and climate parameters could not be eliminated in relation to ambient air Pb concentrations. Such mechanisms are described in more detail in Section 3.3. As described in Sections 3.2.2.6 and 3.6.1, there are many contemporary contributions of Pb to soil in urban areas, and studies summarized here have not quantitatively differentiated the contributions of these various sources to Pb concentrations in urban areas.

Pb from Industrial Activities

Several studies have indicated elevated levels of Pb are found in soil exposed to industrial emissions, including brownfield sites (Dermont et al., 2010; Verstraete and Van Meirvenne, 2008; Jennings and Ma, 2007; van Herwijnen et al., 2007; Deng and Jennings, 2006). Pb in industrial soils is described in Section 3.6.1. Recent Pb speciation results also indicate a contribution from resuspended soils in areas with previous major emission sources, but without current major sources. Data from airborne PM in the vicinity of an inactive smelter in El Paso, TX were described as consistent with Pb-humate as the major form of Pb in airborne PM, which the authors suggest relates to soil resuspension since the local near-surface soils appeared to have had high humic content (Pingitore et al., 2009).

Pb from Paint and Building Materials

Exterior structures painted with Pb-based paint have long been known to be a source of Pb in outdoor dust or grit (U.S. EPA, 2006b). Recent studies support earlier findings. Mielke and Gonzales (2008) sampled exterior paint chips from paint applied prior to 1992 on 25 homes in New Orleans, LA, and they found elevated Pb levels in 24 of the 25 tested exterior paints. Weiss et al. (2006) studied the distribution of Pb concentration in roadway grit in the vicinity of steel structures in New York City and contrasted those data with roadway grit concentration data where no steel structure was nearby. In each case, the difference was significant ($p < 0.006$ at one site and $p < 0.0001$ at 4 other sites), with median Pb concentrations in the grit under the steel structures (median: 1,480 mg/kg) collectively being 4.4 times higher than median Pb concentrations in the roadway grit not near a structure (median: 340 mg/kg).

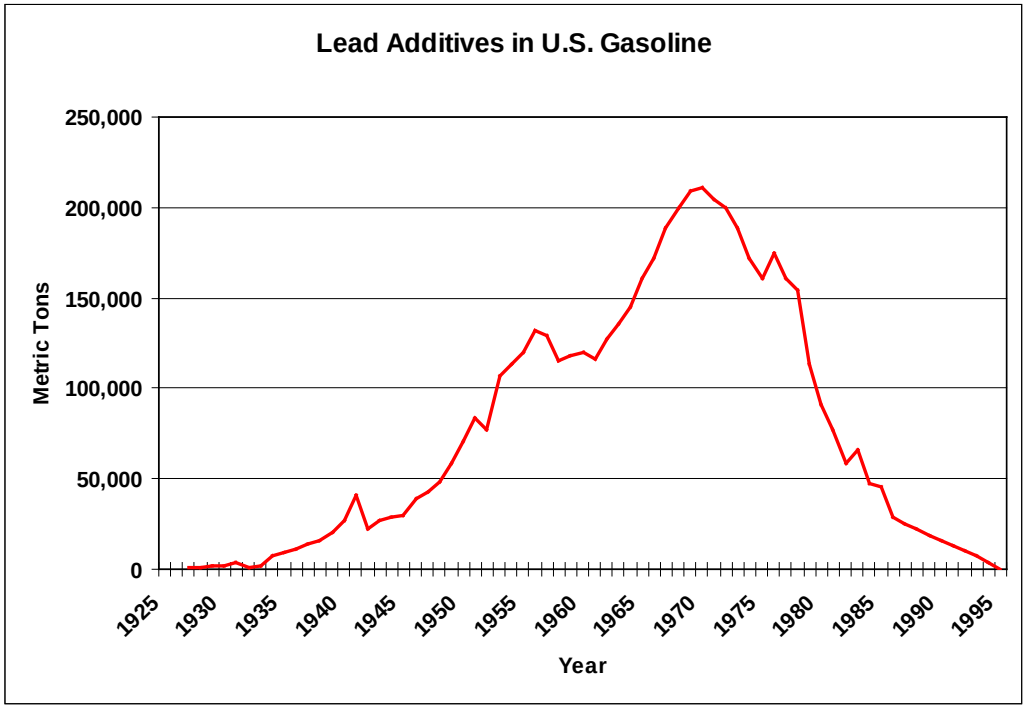
The studies described above considered paint as a source of Pb in outdoor dust through gradual abrasion of the painted surfaces. However, atmospheric conditions may break down polymers in aging paint, causing previously bound Pb-based pigments to be released from the surface more readily. Edwards et al. (2009) performed experiments to simulate one week of exposure of Pb-based paints to highly elevated levels of O_3 (11.3 ± 0.8 mg/kg or 150 times the level of the 8-hour NAAQS) and NO_2 (11.6 ± 0.9 mg/kg, or 220 times the level of the annual NAAQS). Following NO_2 exposure, the Pb in wipe samples increased by a median of 260% ($p < 0.001$), and following O_3 exposure, the Pb in wipe samples increased by a median of 32% ($p = 0.004$).

Building demolition was listed as a source of Pb in urban dust in the 2006 Pb AQCD (U.S. EPA, 2006b). In a follow-up study to previous work cited therein, Farfel et al. (2005) observed that surface loadings of dust containing Pb increased by 200% in streets, by 138% in alleys, and by 26% in sidewalks immediately following demolition of an old building compared with surface loadings of dust containing Pb prior to demolition. One month later, Pb dust loadings were still elevated in alleys (18% higher than pre-demolition) and sidewalks (18% higher than pre-demolition), although they had decreased in streets by 29% compared with loadings prior to demolition. However, Farfel et al. (2005) did not provide detailed time series samples from before or after demolition to judge whether the observations made one month following demolition were within the normal conditions of the urban area. These results suggest that building demolition may be a short-term source of Pb in the environment, but it is unclear if demolition is related to long-term Pb persistence in the environment.

Pb from Historic Automobile Emissions

Historic Pb emissions, or Pb emitted from on-road vehicles prior to the ban on use of leaded automobile gasoline, deposited onto soil and in some areas may serve as a potential source of airborne Pb. The historical use of leaded on-road gasoline has been estimated from documents submitted by Ethyl Corporation to the U.S. Senate (1984) and a report by the U.S. Geological Survey (USGS, 2005); see Mielke et al. (2011c). These estimates are presented in Figure 3-7. The peak U.S. use of Pb additives occurred between 1968 and 1972 with an annual amount of over 200,000 metric tons. According to Ethyl Corporation, the 1970 use of Pb additives was 211,000 metric tons. By 1980, the annual use of Pb additives to on-road gasoline decreased to about 91,000 metric tons or a 57% reduction from its 1970 peak. From 1970 to 1990 there was a 92% decline in Pb additive use. In 1990, the annual U.S. use of Pb additives decreased to 16,000 metric tons, a further 82% decline in Pb additive use from 1980. The final U.S. ban on the use of Pb additives for highway use in on-road gasoline occurred in 1996.

After that time, Pb additives were only allowed in nonroad applications, including piston-engine aircraft fuel, racing fuels, farm tractors, snowmobiles, and boats.



Note: Estimates were derived from the proceedings of the U.S. Senate hearings on the Airborne Pb Reduction Act of 1984, S. 2609 (1984) and the U.S. Geological Survey Pb end use statistics (USGS, 2005).

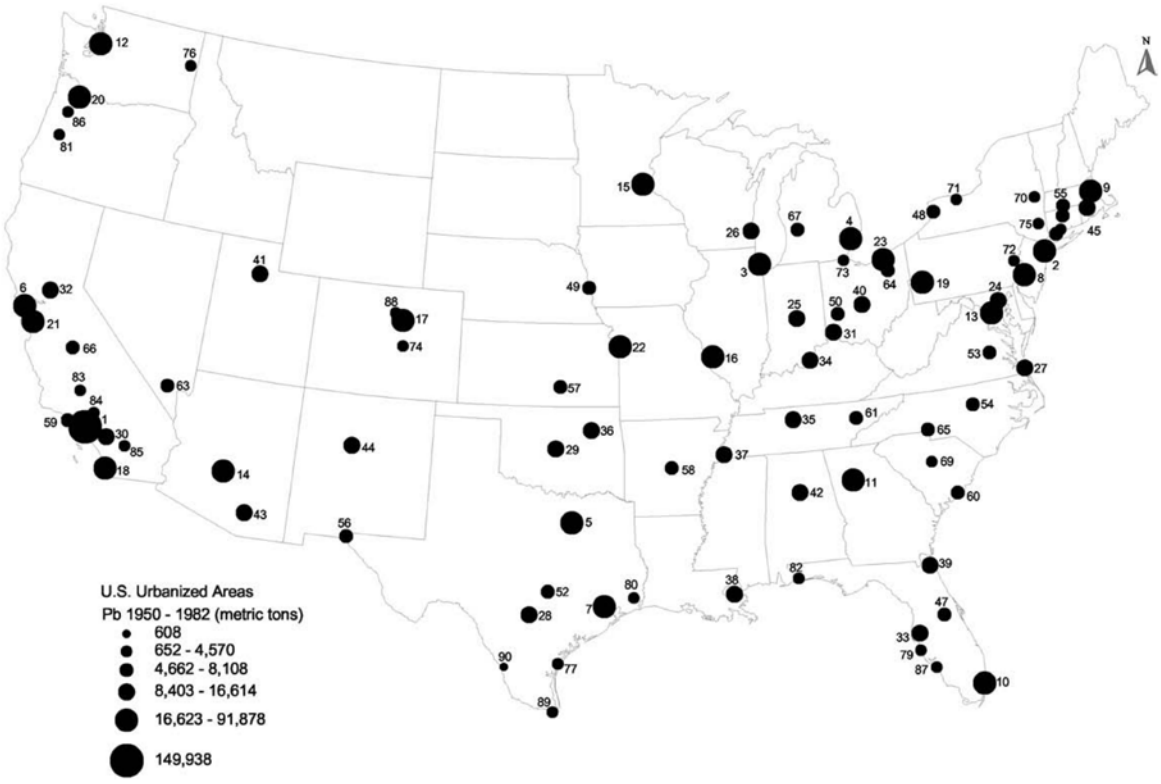
Source: Reprinted with permission of Pergamon Press, Mielke et al. (2011c).

Figure 3-7 Total U.S. Pb additives in on-road gasoline used in on-road vehicles, 1927-1995.

Pb emissions from on-road sources were estimated by the U.S. EPA (1986a), which indicated that 75% of Pb additives were emitted as exhaust, while the remainder were retained within the engine. The tonnages of relatively large >10 µm mass median aerodynamic diameter (MMAD) Pb-PM probably settled locally. EPA (1986a) indicated that 35% of the Pb-PM at that time were <0.25 µm in MMAD. In high traffic urbanized areas, soil Pb from historic emissions as well as contemporary sources, are elevated adjacent to roadways and decrease with distance away from roadways (Laidlaw and Filippelli, 2008).

The use of Pb additives resulted in a national scale of influence. For example, variously sized urbanized areas of the U.S. have different amounts of vehicle traffic associated with Pb (Mielke et al., 2010). Figure 3-8 illustrates the national scale of the estimated vehicle-derived Pb aerosol emissions. Note that the estimated 1950-1982 Pb aerosol emissions in the 90 cities below vary from 606 metric tons for Laredo, Texas, to nearly

150,000 metric tons for the Los Angeles-Long Beach-Santa Anna urbanized area. Although this figure might imply that the soil Pb concentration in these areas would be proportional to the magnitude of historic on-road emissions in each city, it is recognized that the atmospheric dispersion of emissions, as well as the atmospheric deposition and subsequent distribution associated with surface runoff, will have varied substantially among the cities illustrated. Additionally, the amount of soil turnover since 1982 may have varied substantially among the cities illustrated in Figure 3-8, depending on the amount of highway construction in those cities. As noted in Section 3.2.2.6 , there have historically been, and are currently, many additional sources of Pb contributing to near-roadway soil Pb concentrations. Data are lacking that quantify the range of airborne Pb concentrations originating from historic Pb in resuspended soil particles, but data on airborne concentrations near roadways indicate measured air Pb concentrations (from all contributing sources) to be generally less than 0.02 μg/m^3 (Section 3.5.3.2).



Note: The numbers on the map are rankings of each urbanized area (UA). The size of each dot refers to the magnitude of motor vehicle gasoline-related emissions for each group of UAs.

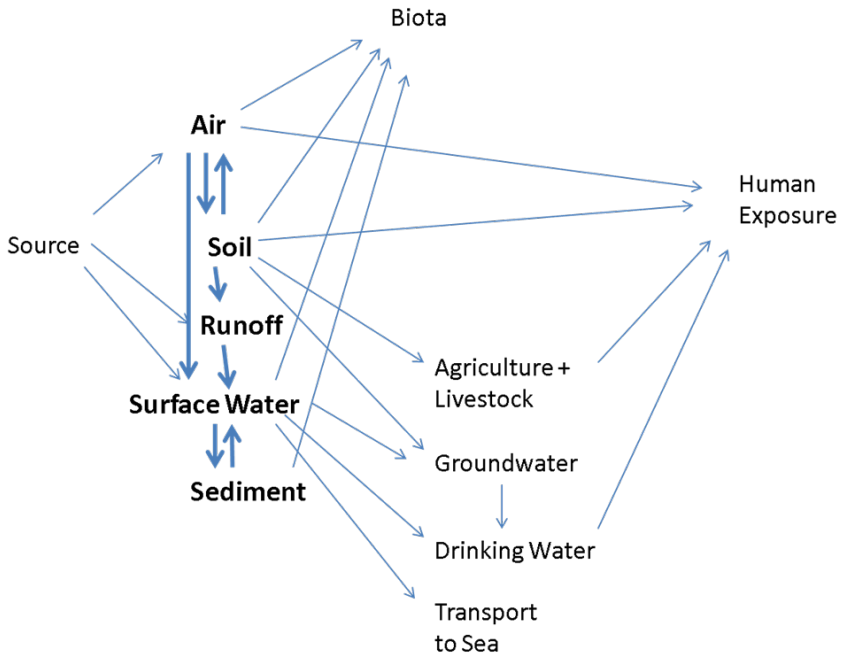
Figure 3-8 Estimated Pb aerosol inputs from on-road gasoline into 90 U.S. urbanized areas (UAs), from 1950 through 1982.

3.3 Fate and Transport of Pb

There are multiple routes of exposure to Pb, including direct exposure to atmospheric Pb, exposure to Pb deposited in other media after atmospheric transport, and exposure to Pb in other media that does not originate from atmospheric deposition. As a result, an understanding of transport within and between media such as air, surface water, soil, and sediment is necessary for understanding direct and indirect impacts of atmospheric Pb as well as the contribution of atmospheric Pb to total Pb exposure. Figure 3-9 describes relevant Pb transport pathways through environmental media discussed in this chapter and their relationship to key environmental and human exposure pathways for which some or all of the Pb is processed through the atmosphere. This discussion includes recent research on atmospheric transport of Pb, atmospheric deposition and resuspension of Pb, Pb transport in surface waters and sediments, and Pb transport in soil. Facets of fate and transport relevant to the ecological effects of Pb are also summarized in Section 7.2.



Note: Media through which Pb is transported and deposited are shown in bold.

Figure 3-9 Fate of atmospheric Pb.

3.3.1 Air

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that Pb was primarily present in submicron aerosols, but that bimodal size distributions were frequently observed. Pb-PM in the fine fraction is transported long distances, found in remote areas, and can be modeled using Gaussian plume models and Lagrangian or Eulerian continental transport models as reported by several studies. Good agreement between measurements and these models have been reported. Historical records of atmospheric deposition to soil, sediments, peat, plants, snowpacks, and ice cores have provided valuable information on trends and characteristics of atmospheric Pb transport. Numerous studies using a variety of environmental media indicated a consistent pattern of Pb deposition peaking in the 1970s, followed by a more recent decline. These findings indicated that the elimination of leaded gasoline for motor vehicles and systematic reductions in emissions from other Pb sources has not only led to lower atmospheric concentrations in areas impacted by vehicles (Section 3.5), but a pervasive pattern of decreasing atmospheric Pb deposition and decreasing concentrations in other environmental media even at great distances from sources.

3.3.1.1 Transport

Recent research on long range transport as well as transport of Pb in urban areas has advanced the understanding of Pb transport in the atmosphere. While the 2006 Pb AQCD described long range Pb transport as essentially a process of submicron PM transport (U.S. EPA, 2006b), much of the recent research on Pb transport has focused on interactions between anthropogenic and coarser geogenic PM that leads to incorporation of Pb into coarse PM as well as subsequent transformation on exposure to mineral components of coarse PM. Using scanning electron microscopy (SEM), Schleicher et al. (2010) observed interactions of anthropogenic soot and fly ash particles on the surfaces of coarse geogenic mineral particles in Beijing, China and concluded that toxic metals were often associated with TSP. Murphy et al. (2007) found that PM released from wild fires and transported over long distances scavenged and accumulated Pb and sulfate through coagulation with small Pb rich PM during transport and that Pb was associated with PM over a wide size range. Erel et al. (2006) also found that Pb enrichment factors calculated for PM_{10} from dust storms collected in Israel were much greater than those sampled at their north African source, suggesting that the dust samples had picked up pollutant Pb in transit between the Saharan desert and Israel. Marx et al. (2008) characterized dust samples collected from the surface of glaciers and in dust traps on the remote west coast of New Zealand's South Island and observed that most of the dust

samples were enriched in metals, including Pb, compared with their source area sediments.

Pb accumulated on mineral dusts is also subject to atmospheric transformations. $PbSO_4$ is one of the main constituents of Pb-containing aerosols resulting from coal combustion (Gieré et al., 2006) and it has been shown to react with calcite, $CaCO_3$, a PM mineral component, to form $Pb_3(CO_3)_2(OH)_2$, $Pb(CO_3)$ and $Ca(SO_{4)2}{\cdot}H_2O$ on the surface of the calcite (Falgayrac et al., 2006). In laboratory experiments, (Ishizaka et al., 2009) also showed that $PbSO_4$ could be converted to $PbCO_3$ in the presence of water. Approximately 60-80% was converted after only 24 hours for test samples immersed in a water droplet. This compared with only 4% conversion for particles that had not been immersed. As a result of recent research, there is considerable evidence that appreciable amounts of Pb can accumulate on coarse PM during transport, and that the physical and chemical characteristics of Pb can be altered by this process due to accompanying transformations.

3.3.1.2 Deposition

The 2006 Pb AQCD (U.S. EPA, 2006b) documented that soluble Pb was mostly removed by wet deposition, and most of the insoluble Pb was mostly removed by dry deposition. As a result, dry deposition was the major removal mechanism for Pb in coarse PM (which is mainly insoluble and settles faster than fine PM), and wet deposition was the most important removal mechanism for fine PM and Pb halides (which were more soluble). Numerous studies reported that Pb dry deposition velocities in the U.S. were mostly within a range of 0.05 to 1.0 cm/sec and dry deposition fluxes ranging from 0.04 to 4 $mg/m^2{\cdot}yr$. Precipitation concentrations ranged mostly from 0.5 to 60 µg/L, but with considerably lower concentrations in remote areas, and wet deposition fluxes in the U.S. ranged from 0.3 to 1.0 $mg/m^2{\cdot}yr$. Wet deposition was linked to precipitation intensity, with slow even rainfalls usually depositing more Pb than intense rain showers. Rain concentrations decreased dramatically between the early 1980s and the 1990s, reflecting the overall decreasing trend in Pb emissions due to elimination of leaded motor vehicle gasoline. A summary of studies investigating total deposition including both wet and dry deposition indicated typical deposition fluxes of 2-3 $mg/m^2{\cdot}yr$ and dry to wet deposition ratios ranging from 0.25 to 2.5. Seasonal deposition patterns can be affected by both variations in local source emissions and vegetation cover, and as a result a consistent seasonal pattern across studies has not been observed, although there have been only a few investigations. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that resuspension by wind and traffic contribute to airborne Pb near sources.

Wet Deposition

The 2006 Pb AQCD (U.S. EPA, 2006b) documented that dry deposition was the major removal mechanism for Pb in coarse PM and wet deposition as the most important removal mechanism for fine PM. Which process is most important for atmospheric removal of metals by deposition is largely controlled by solubility in rain water. Metal solubility in natural waters is determined by a complex multicomponent equilibrium between metals and their soluble complexes and insoluble ionic solids formed with hydroxide, oxide, and carbonate ions. This equilibrium is strongly dependent on pH and ionic composition of the rain water. As pH increases, Pb solubility is reduced. Theodosi et al. (2010) found that solubility of Pb was near 100% when rain water pH was measured to be less than 4.5. As a consequence, it is possible that efforts to reduce acidity of precipitation could also reduce wet deposition of Pb. Recent research confirms the general trend described in the 2006 Pb AQCD (U.S. EPA, 2006b) that Pb associated with fine PM is usually more soluble in rain water than Pb associated with coarse PM, leading to a relatively greater importance of wet deposition for fine Pb and of dry deposition for coarse Pb. Theodosi et al. (2010) concluded that larger particles were less soluble, because Pb solubility decreased with increasing dust loading. Likewise, Preciado and Li (2006) observed that solubility decreased with increasing particle size. Moreover, Theodosi et al. (2010) observed that 53% of wet deposition samples were comprised of particulate Pb, not soluble Pb. This finding suggests that wash-out can be equally important to wet deposition as solubility.

Although recent observations are consistent with previous findings, they also indicate considerable spatial and seasonal variability. Birmili et al. (2006) found that Pb solubility varied between the two main Pb-containing size fractions, <0.5 μm (~40%) and 1.5-3.0 μm (~10%), indicative of a different chemical speciation. However, the observation that the amount of soluble Pb was higher in their U.K. samples than in an analytically identical study carried out in Seville, Spain (Fernandez Espinosa et al., 2004), led them to conclude that Pb solubility in fine PM may vary on a regional basis (Birmili et al., 2006). For PM_{10} from Antarctica, 90 to 100% of the Pb was insoluble at the beginning of the summer season (November), but by the end of the summer (January), approximately 50% was soluble. Most of the Pb was from long range transport (Annibaldi et al., 2007). These studies illustrate the variable nature of atmospheric Pb solubility.

Dry Deposition

Recent research on dry deposition has focused differences between urban or industrial sites and rural or less industrial areas. For locations outside of industrial areas, new measurements of Pb dry deposition fluxes are similar to those reported in the 2006 Pb AQCD (U.S. EPA, 2006b), but in industrialized urban areas, they are considerably greater than in nonindustrialized areas. Deposition is typically documented by measurements of Pb concentrations on surface material or by measurements of flux. For example, Hasselbach et al. (2005) documented Pb concentration in moss, and the spatial distribution of Pb concentration in moss, as evidence of Pb deposition from truck traffic between an Alaskan Zn-Pb mine and a port. Additionally, Maher et al. (2008) measured Pb deposition onto leaves near a road in Norwich, U.K. Their results are described in detail in Section 3.6.6.

Several studies presented measurements of dry deposition flux obtained by capturing deposited particles onto a sampling substrate. Hence, these measurements did not provide information on net deposition following resuspension of deposited material. Resuspension processes and measurements thereof are described in Section 3.3.1.3. For example, Yi et al. (2006) calculated dry deposition fluxes for trace elements including Pb in New York-New Jersey harbor and observed much greater dry deposition fluxes for this urban industrial site in Jersey City (mean: 50 $\mu g/m^2 \cdot day$) than for suburban New Brunswick (mean: 8 $\mu g/m^2 \cdot day$). Sabin and Schiff (2008) measured dry Pb deposition flux along a transect from Santa Barbara to San Diego, CA in 2006 and observed a range of 0.52-14 $\mu g/m^2 \cdot d$ for the median values across the eight sites. The highest median Pb flux was observed at Los Angeles Harbor, which is downwind of a harbor with a mix of industrial (harbor-related) and urban activities (14 $\mu g/m^2 \cdot day$). The second highest median Pb flux was observed at San Diego Bay, a military port (3.3 $\mu g/m^2 \cdot day$). This is consistent with similar observations of dry deposition fluxes that were more than ten times greater in urban Chicago than in rural South Haven, Michigan (Paode et al., 1998). These results illustrate the strongly localized nature of atmospheric Pb deposition in source rich areas.

Elements from anthropogenic sources, including Pb, were generally associated with fine PM. In a study of Tokyo Bay (Sakata and Asakura, 2008), reported an average dry deposition velocity of 1.06 cm/sec, which is at the upper end of dry deposition velocities reported in the 2006 Pb AQCD (U.S. EPA, 2006b). They also reported that dry deposition fluxes were greater in industrially impacted urban areas, ranging from 12-17 $mg/m^2 \cdot yr$, more than 10 times the upper bound of the range reported in the 2006 Pb AQCD (U.S. EPA, 2006b).

Recent results also confirmed the trend of decreasing overall deposition fluxes after removal of Pb from on-road gasoline, as described in the 2006 Pb AQCD (U.S. EPA, 2006b). Watmough and Dillon (2007) found that the bulk annual deposition of Pb in a central Ontario forested watershed during 2002-2003 was 0.49 $mg/m^2 \cdot yr$; this was lower than the value of 1.30-1.90 $mg/m^2 \cdot yr$ for 1989-91 and represented a 75% decline in Pb deposition. It was consistent with the decline more generally observed for the Northeastern U.S. as a consequence of the restrictions to alkyl-Pb additives in on-road gasoline. From previously published work, and in agreement with the precipitation data described above, most of the decline in Ontario Pb deposition took place before the start of the Watmough and Dillon (2007) study.

Within-day variation in deposition fluxes was observed to be related to the urban boundary layer. Lim et al. (2006) observed higher deposition fluxes of Pb and other transition metals during the nighttime in Los Angeles, when inversions are frequent occurrences. Deposition mass was also greater for particles larger than 10 μm in the urban areas where measurements occurred. Larger particle deposition flux was greater during the day, indicating that the source was anthropogenic.

Several important observations can be highlighted from the few studies of atmospheric Pb deposition carried out in the past several years. Deposition fluxes have greatly declined since the removal of Pb additives from on-road gasoline. However, more recent results in industrial areas indicate that local deposition fluxes there are much higher than under more typical conditions. In general, wet deposition appears to be more important for Pb in fine PM, which is relatively soluble; and dry deposition appears to be generally more important for Pb in coarse PM, which is relatively insoluble. However, the relative importance of wet and dry deposition is highly variable with respect to location and season, probably reflecting both variations in Pb speciation and variations in external factors such as pH and rain water composition. Although industrial Pb emissions are mainly associated with fine PM, and wet deposition is likely to be more important for this size range, a substantial amount of Pb is apparently removed near industrial sources.

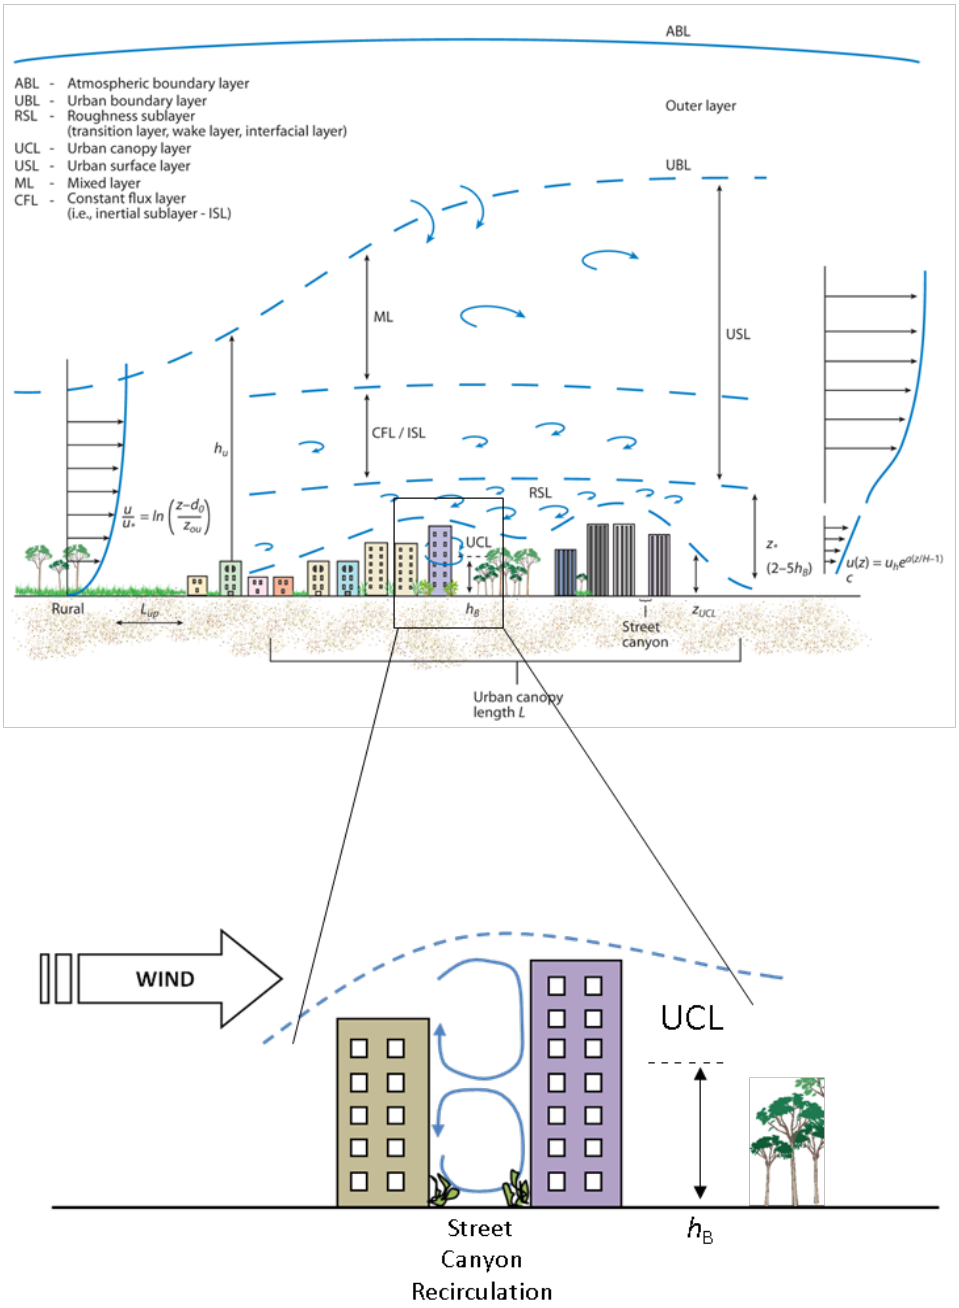
3.3.1.3 Resuspension of Pb from Surface Soil to Air after Deposition

The following information focuses on issues regarding the transport processes affecting resuspended soil Pb and dust Pb in urban environments. As described in Section 3.2.1, the greatest point source Pb emissions in the U.S. occur in locations near specific major facilities, such as secondary smelters, and other industrial operations involving large scale metal processing or fuel combustion. However, in the absence of such sources and

in the vicinity of previous major sources, the 2006 Pb AQCD (U.S. EPA, 2006b) concluded that resuspension by mechanical stressors such as traffic, construction, and wind can be a source of airborne Pb above background levels near sources, with Pb accounting for between 0.002 to 0.3% of the mass of resuspended PM_{10}. Reentrainment of deposited Pb complicates air related pathways of human (Section 4.1.1) and ecosystem exposure (Section 7.2.2).

Results from several studies have suggested minor contributions from resuspension to airborne Pb concentration from various sources, including city centers (Laidlaw and Filippelli, 2008), major freeways (Sabin et al., 2006b), and steel structures with abrading paint (Weiss et al., 2006). Recently, Laidlaw et al. (2012) modeled concurrent measurements of (log-transformed) air Pb-$PM_{2.5}$ as a function of (log-transformed) airborne soil measured in $PM_{2.5}$. They observed a marginal but statistically significant increase in air Pb of 0.84% with a 1% increase in airborne soil ($p < 0.01$). As noted in the 2006 Pb AQCD (U.S. EPA, 2006b), the contribution of resuspended soil and dust to the airborne burden may be significant from highly contaminated sites (e.g., active or abandoned industrial facilities and Superfund sites). In contrast, as summarized in Section 3.5.3, Pb concentrations near roads in urban areas are one to two orders of magnitude below the current Pb NAAQS.

The urban environment can be considered quite different from natural landscapes because it has been highly modified by human activity, including above- and below-ground infrastructure, buildings, and pavement, and a high density of motorized transportation. These factors may influence the distribution and redistribution of Pb-bearing PM. As shown in Figure 3-10, urban turbulence occurs on several scales. Transport and dispersion of urban grit is subject to air movement within the urban canopy layer, where air movement is driven by air velocity within the urban boundary layer and urban topographical conditions such as building shape, building façade, and street canyon aspect ratio (Fernando, 2010). Within a street canyon, air circulates and tends to form counter-rotating eddies along the height of the canyon (Figure 3-10), which result in lower mean components of air movement, higher turbulence components, and higher shear stress within the canyon compared with open field conditions (Kastner-Klein and Rotach, 2004; Britter and Hanna, 2003). Recirculation around intersection corners and two-way traffic conditions can also enhance turbulence levels, while one-way traffic conditions increase air velocity along the street (Soulhac et al., 2009; Kastner-Klein et al., 2003; Kastner-Klein et al., 2001). Sedefian et al. (1981) measured the length scales of turbulent eddies resulting from passing 50 mph (22.2 meters/seconds) traffic on a test road and observed scales of 0.6-2.7 meters when winds were perpendicular to the test road and scales of 1.8-2.7 meters when winds were parallel to the road.



Note: Top: multiple scales within the atmospheric boundary layer. Bottom: illustration of airflow recirculation within a single street canyon located in the urban canopy layer.

Figure 3-10 Scales of turbulence within an urban environment.

Recent research on urban PM transport is highly relevant to Pb transport and dispersion because Pb is most prevalently particle-bound. Relevant results for Pb exposure in these areas include observations that PM concentration peaks dissipate more rapidly on wider streets than in narrow street canyons (Buonanno et al., 2011); concentrations are typically low next to a building because either less source material is available or less material penetrates the boundary layer of the building (Buonanno et al., 2011); and there are stronger inverse relationship between mean wind speed and PM concentration fluctuation intensities at middle sections of urban street blocks compared with intersections (Hahn et al., 2009). Patra et al. (2008) conducted experiments in London, U.K. in which a "tracer" grit (i.e., rock salt) was applied to a road and then the grit's dispersion by traffic was measured over time to simulate resuspension and transport of road dust. During the experiments, 0.039% of the tracer grit was measured to move down the road with each passing vehicle, 0.0050% was estimated to be swept across the road with each passing vehicle, and 0.031% was estimated to become airborne when a vehicle passed.

Harris and Davidson (2008) developed a model of resuspension of single particles initially at rest on a solid surface based on the balance of lift, drag, gravity, torque, and adhesion forces on the particle in addition to turbulent wind fluctuations within a simulated urban boundary layer. In their model simulations showed 2.5 µm and 10 µm particles to reach a maximum height of 0.04-0.06 meter above ground level (AGL), while 50 µm particles reached a maximum of 0.2 meter AGL and 75 µm particles reached at least 0.4 meter AGL, depending on friction velocity. Empirical analysis has shown that lift force is proportional to particle diameter to the power of approximately 1.5, so that large particles actually have larger initial vertical displacement than smaller particles. At the same time, lateral travel distance following resuspension tended to decrease linearly with increasing particle size, reflecting the counteracting force of gravity. For all cases simulated, the resuspension and deposition were estimated to occur over time frames on the order of seconds.

Early work described resuspension as an important process for wind erosion for particles up to 100 µm, but indicated that particles larger than this rarely became suspended, and that the tendency of particles to remain airborne long enough for appreciable transport decreases sharply beyond a size of 10 to 20 µm (Nicholson, 1988; Gillette et al., 1974). As a result, long range transport of dust is usually limited to particles smaller than 10 µm (Prospero, 1999).

In urban environments the transport distance that must be traversed to penetrate indoors can be very short, and at the same time resuspension and dispersion of larger particles may be caused by motor vehicles. Resuspension of road dust by traffic becomes more difficult with decreasing particle size because adhesive forces are stronger than shear

force that is imparted by traffic-induced turbulent air movement (Harris and Davidson, 2008). The critical diameter at which resuspension occurs when a particle's settling velocity becomes lower than the friction velocity of air needed to move the particle from rest. The work of Gillette et al. (1974), in which a critical diameter of roughly 20 µm was estimated, is based on wind in an open landscape. It would be reasonable to expect that friction velocity would be higher for urban environments with traffic-induced turbulence (Britter and Hanna, 2003). Hence, it is possible that larger particles are resuspended in a heavily-trafficked urban setting (Nicholson and Branson, 1990).

Particle size determines the distance particles can travel and the height which they can achieve before they are removed by gravitational settling. Song and Gao (2011) observed that coarse mode Pb concentration was negatively correlated with wind speed (D_p = 14: ρ = -0.62; D_p = 7.8; ρ = -0.76), which suggests that coarse Pb may be dispersed by wind. Observations in near road environments indicate that roughly 15% of Pb in airborne dust in areas impacted by heavy traffic is greater than 10 µm (Cho et al., 2011; Lough et al., 2005; Zereini et al., 2005). Sabin et al. (2006b) also collected three size fractions greater than 11 µm and found that approximately 25% of all Pb mass was associated with particles larger than 29 µm at a site 10 meters from a freeway, but only a very small percentage of Pb mass was in this size fraction at an urban background site. These results suggest that both size distribution and concentrations in the immediate vicinity of roadways might differ from estimates based on concentrations from monitoring sites at some distance from roads or on elevated rooftops. In these studies, only one size fraction slightly greater than 10 µm was collected, but another study of road dust (not specific to Pb) reported size fractions extending up to 100 µm with a mass median diameter of greater than 60 µm (Yang et al., 1999). Although the Yang et al. (1999) study did not include Pb, the results suggest that resuspended dust can be larger than PM_{10}. Collectively, the size distribution of Pb-containing resuspended dust is uncertain.

Recent resuspension studies complement previous research indicating street dust half-lives on the order of one-hundred days (Allott et al., 1989), with resuspension and street run-off as major sinks (Vermette et al., 1991) as well as observations of a strong influence of street surface pollution on resuspension (Bukowiecki et al., 2010), observations of greater resuspension of smaller PM than coarser PM, leading to enrichment of metal concentrations in resuspended PM relative to street dust (Wong et al., 2006) and observations of wind speed, wind direction, vehicular traffic, pedestrian traffic, agricultural activities, street sweeping and construction operations as important factors determining resuspension.

3.3.2 Water

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), atmospheric deposition, urban runoff, and industrial discharge have been identified as major sources of Pb in surface waters. Water columns have been described as transient reservoirs with Pb residence times in lakes typically several months long, and shorter residence times expected in turbulent waterways. Because dispersal in waterways is a relatively rapid process, concentrations in surface waters are highest near sources of pollution before substantial Pb removal by flushing, evaporation, and sedimentation occurs. Transport in surface water is largely controlled by exchange with sediments, and the cycling of Pb between water and sediments is governed by chemical, biological, and mechanical processes that are affected by many factors, including salinity, organic complexation, oxidation-reduction potential, and pH; ecological impacts of these factors are described in Section 7.4.9. As described in the 2006 Pb AQCD (U.S. EPA, 2006b), metals in waterways are transported primarily as soluble chelates and ions, or adsorbed on colloidal surfaces, including secondary clay minerals, iron and manganese oxides or hydroxides, and organic matter, and adsorption on organic or inorganic colloids is particularly important for Pb. The extent of sorption strongly depends on particle size as smaller particles have larger collective surface areas. Aqueous Pb concentrations also increase with increasing salinity. Pb is found predominantly as PbO or $PbCO_3$ in aqueous ecosystems. Pb is relatively stable in sediments, with long residence times and limited mobility. However, Pb-containing sediment particles can be remobilized into the water column. As a result trends in sediment concentration tend to follow those in overlying waters. Fe and Mn oxides are especially susceptible to recycling with the overlying water column. Although resuspension of sediments into overlying waters is generally small compared to sedimentation, resuspension of contaminated sediments is often a more important source than atmospheric deposition. Organic matter (OM) in sediments has a high capacity for accumulating trace elements. In an anoxic environmental removal by sulfides is particularly important. The following section highlights recent literature regarding the fate and transport of Pb in water systems. Section 7.2 synthesizes this information with ecosystem exposure data.

Runoff from storms was identified as an important source of Pb in aquatic systems (U.S. EPA, 2006b). Runoff from atmospheric deposition, buildings due to paint, gutters, roofing materials and other housing materials were identified as major contributors to Pb in runoff waters. Investigations of building material contributions indicated runoff concentrations ranging from 2 to 88 mg/L, with the highest concentrations observed from more than 10-year-old paint and the lowest concentrations from residential roofs. There was some indication that Pb from roofing materials, siding, and piping could be due to dissolution of Pb carbonate (cerussite) or related compounds. In several studies Pb in

runoff was consistently mostly PM, with a relatively small dissolved fraction. Runoff release was dependent on storm intensity and length of dry periods between rain events, with greater runoff of Pb associated with more intense storms and with longer periods between rain events. Several studies indicated a "first flush effect," with highest runoff concentrations observed at the beginning of a rain event.

3.3.2.1 Pb Transport in Water and Sediment

Recent publications provide additional detail regarding Pb adsorption on iron rich and organic rich colloids. Correlation between Pb concentration in unfiltered water with total Fe was observed (Hassellov and von der Kammer, 2008), which is consistent with previous research using cross flow filtration (Pokrovsky and Schott, 2002; Ross and Sherrell, 1999) and SEM examination of single particles (Taillefert et al., 2000).

Two distinct colloidal phases, one organic-rich (0.5-3 nm in diameter) and the other Fe-rich (>3 nm in diameter), have been observed to coexist in both soil isolates and river water (Stolpe and Hassellov, 2007). Pb was observed to be predominantly associated with Fe-oxide PM in river water but also associated with the organic colloids in the soil isolates (Hassellov and von der Kammer, 2008). Investigation of Pb binding onto ferrihydrite showed Pb binding data were consistent with Pb being held at the surface by sorption processes, rather than enclosed within the particle structure (Hassellov and von der Kammer, 2008).

Observations in boreal rivers and soil pore waters in permafrost dominated areas of Central Siberia indicated that Pb was transported with colloids in Fe-rich waters. Trace elements that normally exhibited limited mobility (including Pb) had 40-80% of their annual flux in the nominal dissolved phase, operationally defined as material that passes through a 0.45 µm pore-size filter, and that these metals had a higher affinity for organo-mineral Fe-Al colloids (Pokrovsky et al., 2006). Pokrovsky et al. (2006) postulated that during the summer, rainwater interacts with degrading plant litter in the top soil leading to the formation of Fe-Al-organic colloids with incorporated trace elements. Migration of trace element-Fe-Al-OM colloids may result in export of Pb and other elements to riverine systems. Most of the transport occurred after thawing had commenced. This contrasts with permafrost free areas where trace elements such as Pb are incorporated into iron colloids during OM-stabilized Fe-oxyhydroxide formation at the redox boundary of Fe(II)-rich waters and surficial DOC-rich horizons. Similarly, during a spring flood (May) that exported 30-60% of total annual dissolved and suspended flux of elements including Pb, Pb was mainly in the nominal dissolved phase, operationally defined as material that passes through a 0.45 µm pore-size filter (Pokrovsky et al.,

2010). Pb adsorbed on colloidal surfaces rather than incorporated into particle structure is likely to be more readily dissolved because dissolution of the entire particle is not required.

Recent research on retention of Pb in water bodies and sediments has focused on the estuarine and marine environment, where considerable retention of Pb was observed in estuarine sediments. For a large riparian system, the Trinity River, Texas, Warnken and Santschi (2009) found that 80% of riverine Pb was retained in Lake Livingston, an estuarine region, while an additional 16% was removed to estuarine sediments, and only about 4% eventually reached the ocean. Geochemical (sorption by Fe oxyhydroxides), biological (seasonal uptake by sinking algae in Lake Livingston) and hydrological (dilution effects by increasing flow rates) processes were mainly responsible for controlling dissolved trace metal concentrations rather than pollution sources.

Overall, recent research on Pb transport in aquatic systems has provided a large body of observations confirming that Pb transport is dominated by iron and organic rich colloids. In addition, new results indicated that although the 2006 Pb AQCD (U.S. EPA, 2006b) described rivers and lakes as temporary reservoirs with Pb lifetimes of months or less, estuaries can present a substantial barrier to transport into the open ocean.

3.3.2.2 Deposition of Pb within Bodies of Water and in Sediment

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), in general Pb is relatively stable in sediments, with long residence times and limited mobility. As described in previous sections, Pb enters and is distributed in bodies of water largely in PM form. In rivers, particle-bound metals can often account for ≥ 75% of the total load, e.g., (Horowitz and Stephens, 2008). Areas near historically Pb emitting industries and urbanized areas tend to have greater aquatic Pb loads than areas more remote from Pb sources, as several studies have shown the strong positive correlation between population density and river or lake sediment Pb concentrations (Horowitz et al., 2008; Chalmers et al., 2007). Indeed, Chalmers et al. (2007) revealed that in river and lake sediments in New England, there was an order of magnitude difference between Pb sediment concentrations in rural versus urbanized areas.

The fate of Pb in the water column is determined by the chemical and physical properties of the water (pH, salinity, oxidation status, flow rate and the suspended sediment load and its constituents, etc). Desorption, dissolution, precipitation, sorption and complexation processes can all occur concurrently and continuously, leading to transformations and redistribution of Pb. The pH of water is of primary importance in determining the likely chemical fate of Pb in terms of solubility, precipitation or organic

complexation. In peatland areas, such as those in upland areas of the U.K., organic acids draining from the surrounding peatlands can lower stream water pH to below 4. Under these conditions, Pb-PM can be desorbed and released into solution, leading to elevated dissolved Pb concentrations (Rothwell et al., 2008). At the other end of the pH scale, Pb tends to remain or become complexed, precipitated or sorbed to suspended sediments in water, as observed by Das et al. (2008) who studied trace metal geochemistry in a South African lake with water pH of 9. They also found marked differences in Pb concentrations associated with increasing depth in the water column [e.g., the surface Pb-PM concentration of 2 µg/L increased to 60 µg/L at depth and the Pb concentration in the <0.45 µm fraction increased from 2 µg/L at the surface to 19 µg/L at depth (Das et al., 2008)]. This is suggestive of a settlement process in action.

In estuarine and wider marine environments the processes may be more complex because of the additional perturbation caused by tidal action and the strong effects of salinity. Again, PM forms of Pb are important in determining Pb distribution and behavior. Li et al. (2010a) reported that PM Pb accounted for 85 ± 15% and 50 ± 22% in Boston Harbor and Massachusetts Bay, respectively, while Lai et al. (2008b) reported a solid (acid soluble):dissolved Pb ratio of 2.6 for areas of the Australian sector of the Southern Ocean.

The accurate modeling of Pb behavior in marine waters (including estuaries) requires consideration of many parameters such as hydrodynamics, salinity, pH, suspended PM, fluxes between PM and dissolved phases (Hartnett and Berry, 2010). Several new advances in the study of Pb cycling in these complex environments have been described in recent publications. Li et al. (2010a) used particle organic carbon (POC) as a surrogate for the primary sorption phase in the water column to describe and model the partitioning of Pb between PM and dissolved forms. Huang and Conte (2009) observed that considerable change in the composition of PM occurs as they sink in the marine environment of the Sargasso Sea, with mineralization of OM resulting in increased Pb-PM concentration with increased depth. As a result of this depletion of OM in sinking particles, geochemical behavior at depth was dominated by inorganic processes, e.g., adsorption onto surfaces, which were largely independent of Pb source. Sinking rates in marine environments can vary, but a rate approximating 1 meter/day has been used in some models of Pb transport and distribution in aquatic-sediment systems (Li et al., 2010a). Surface sediment Pb concentrations for various continental shelves were collated and compared by Fang et al. (2009) (Table 3-2).

Table 3-2 Surface sediment Pb concentrations for various continental shelves.

Location	Digestion solution	Pb[a] (mg/kg)
East China Sea	$HCl/HNO_3/HF$	10-49 (27)[a]
Mediterranean, Israel coast	HNO_3	9.9-20
Aegean Sea	$HCl/HNO_3/HF$	21-44 (34)
Banc d'Arguin, Mauritania	$HCl/HNO_3/HF$	2.8-8.9
Campeche shelf, Gulf of Mexico	HCl/HNO_3	0.22-20 (4.3)
Laptev Sea, Siberia	$HCl/HNO_3/HF$	12-22

3.3.2.3 Flux of Pb from Sediments

Sediments can be either a source or a sink for metals in the aquatic environment. Release can be via re-suspension of the sediment bed via wind, wave and tidal action or by dissolution from sediment to the water column. When external Pb inputs to bodies of water are decreased by environmental improvement actions or regulations, contributions of Pb to the water column from the existing sediments can become an increasingly important source. Roulier et al. (2010) determined that Pb flux from sediments originated mostly from organic fractions, but also partially from Mn and Fe components undergoing reductive dissolution. The rate of release was controlled by OM content, particle size, clay type and content, and silt fraction (Roulier et al., 2010). The importance of sediment particle size, OM content and acid volatile sulfide concentration in relation to metal release was similarly identified (Cantwell et al., 2008); ecosystem effects related to sulfide concentration are described in Section 7.4.2.5. The effect of pH change on Pb release from lake sediments has also been examined, revealing that 1.8 protons (H^+) were exchanged per divalent metal cation released (Lee et al., 2008a). Processes governing Pb release from lake sediments, including microbial reductive dissolution of Fe, biogenic sulfide production and metal sorption-desorption, have been investigated in a basin heavily contaminated by historical precious metal mining activities, and results indicated that release of Pb from suboxic and anoxic zones of the heavily contaminated sediment act as a Pb source to the overlying water of the lake (Sengor et al., 2007). Bacardit and Camarero (2010a, b) performed a mass balance of Pb, Zn, and As for three lakes in the Central Pyrenees in France to identify dominant metals distribution processes. They estimated that flux from the catchment accounted for 91-99% of the lakes' Pb inputs,

while sediment flux accounted for 98-99% of Pb outputs. In this paper, sediment was only modeled as an output.

Disturbance of bed sediments also occurs by tidal action contributing to re-suspension of sediments. Benthic fluxes of dissolved metals released from sediments measured in Boston Bay were calculated as strong enough that in the absence of Pb inputs such benthic flux would reduce sediment Pb concentrations in Boston Bay to background levels in 30-60 years (Li et al., 2010a). In a related way, a half-life for sediment Pb (considering benthic flux alone as the loss mechanism) of 5.3 years was estimated for marine sediments off the Belgian coast (Gao et al., 2009). Atkinson et al. (2007) conducted experiments in an area contaminated by metal smelters, Lake Macquarie, Australia, to assess the factors that influence flux of metals from marine sediment. Low pH (pH = 6 ± 1), bioturbation, and other mixing processes were found to have stronger influence over flux than binding to sulfides, which were thought to be sequestered in deeper sediments.

Radakovitch et al. (2008) investigated the riverine transport of PM including Pb to the Gulf of Lion, France, and also concluded that a major part of annual fluxes could be delivered over a short time period. From budget calculations, riverine inputs were more important than atmospheric deposition and Pb concentrations in the prodelta sediments showed a strong correlation with OM content. These sediments, however, were not considered to be a permanent sink, as resuspension in these shallow areas was an important process. OM, Pb and other metals were enriched in resuspended PM compared with the sediment.

In a heavily contaminated, high salinity embayment upstream from Sydney Harbor in Australia, Birch and O'Hea (2007) reported higher total suspended solids, turbidity and total water metal concentration in surface compared with bottom water as well as a difference in suspended PM metal concentrations between surface water and bottom sediments, demonstrating that stormwater discharge was the dominant process of metal transfer during high rainfall events. Total suspended sediments (and total water metals) in bottom water were higher than in the surface water plume, indicating that resuspension of bottom sediment is a greater contributor of total suspended sediments than stormwater during such events, especially in shallower regions of the bay. Soto-Jimenez and Páez-Osuna (2010) determined diffusive and advective fluxes, geochemical partitioning of Pb and Pb-isotopic signatures in a study of mobility and behavior of Pb in hypersaline salt marsh sediments. They determined that sulfides were the main scavengers for Pb that was diagenetically released Pb.

Overall, recent research on Pb flux from sediments in natural waters provided greater detail on resuspension processes than was available in the 2006 Pb AQCD (U.S. EPA,

2006b), and confirms previous findings that resuspended Pb is largely associated with OM or Fe and Mn particles, but that anoxic or depleted oxygen environments in sediments play an important role in Pb cycling. This newer research confirms previous findings that resuspension and release from sediments largely occurs during discrete events related to storms. It has also confirmed that resuspension is an important process that strongly influences the lifetime of Pb in bodies of water.

3.3.2.4 Pb in Runoff

Runoff is a major source of Pb in surface waters. This complicates any evaluation of the contribution of atmospheric Pb to watersheds, which must take into account direct atmospheric deposition, runoff of atmospherically deposited Pb, and runoff of Pb from sources such as mine tailings or paint chips that are shed from outdoor structures. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that runoff was consistently mostly PM, with a relatively small dissolved fraction, and that dissolution of carbonate and related compounds were important contributors to Pb pollution in runoff waters. It also described runoff Pb release into runoff as dependent on storm intensity and length of dry periods between rain events, and a "first flush effect," with highest runoff concentrations observed at the beginning of a rain event. Subsequent research has provided considerable new information about the flux of Pb from roadway and urban runoff and snow melt to watersheds.

Severe contamination due to export of anthropogenic Pb to adjacent ecosystems via urban runoff and domestic wastewater discharge and to a lesser extent by direct atmospheric deposition has been documented (Soto-Jiménez and Flegal, 2009). Recent investigations also confirm roof runoff as an important contributor to Pb pollution. Huston et al. (2009) measured Pb concentrations in water from urban rainwater tanks and found Pb concentrations in bulk deposition were consistently lower than in water in the rainwater tanks, but that sludge in the tanks had a high Pb content, indicating that not all major sources of Pb are from atmospheric deposition. Pb levels frequently exceeded drinking water standards. Pb flashing on the roofs was implicated as the source of Pb in the rainwater tanks although other possible sources include old paint and Pb stabilized PVC drain pipes (Lasheen et al., 2008; Weiss et al., 2006; Al-Malack, 2001).

New research has improved the understanding of suspended PM size ranges, speciation, and impacts of Pb runoff from urban soil and road dust. Soil and road dust have been identified as major sources of Pb pollution to near-coastal waters, leading to high Pb concentrations in stormwater runoff that became associated with dissolved and suspended

PM phases as well as bedload, material moved by rolling, sliding, and saltating along the bottom of a stream (Birch and McCready, 2009).

Several recent studies reported that the size distribution of PM transported in runoff is relatively uniform. Characterization of the roadside dust in Australia showed that Pb in PM was approximately uniformly distributed among PM size fractions of up to 250 µm. The Pb-containing particles had the potential to be dispersed to some distance into sensitive ecosystems (Pratt and Lottermoser, 2007). Pb in roadside dusts in Thessaloniki, Greece was characterized by Ewen et al. (2009) and no difference in Pb concentration was found between <75 µm and 75-125 µm PM size ranges, although a difference in the chemical form of Pb between slightly versus highly contaminated areas was observed.

Ewen et al. (2009) reported that Pb was mainly in a more exchangeable form (similar to that in an old auto-catalyst reference material) in small particles, but in the residual, or least mobile fraction in larger particles. In urban road dust from Manchester U.K., Pb-bearing Fe-oxides were observed to be dominant in most of the size fractions, and $PbCrO_4$ comprised 8-34% of total Pb with the highest concentrations being found in the largest and smallest size fractions. $Pb(CO_3)_2$ and $Pb(OH)_2$ were measured in the two middle size fractions, while PbO and $PbSO_4$ were present in the largest and smallest size fractions (Barrett et al., 2010).

Murakami et al. (2007) also emphasized the importance of $PbCrO_4$ as an important species of Pb from road surfaces. That study identified individual particles containing high levels of Pb and Cr (≥ 0.2%), most likely from the yellow road line markings. The identified PM constituted 46% of Cr and Pb in heavy traffic dust and 7-28% in dust from residential areas and soakaway sediments. The presence of such particles in soakaway sediments is consistent with their low environmental solubility.

Recent research also continues to document the first flush effect described in the 2006 Pb AQCD. Flint and Davis (2007) reported that in 13% of runoff events, more than 50% of Pb was flushed in the first 25% of event water. A second flush occurred less frequently (4% of runoff events for Pb). In agreement with the 2006 Pb AQCD (U.S. EPA, 2006b), most recent studies have concluded that, during storm events, Pb is transported together with large PM. Some studies, however, found that Pb was concentrated in the fine PM fraction and, occasionally, Pb was found predominantly in the dissolved fraction. Tuccillo (2006) found that Pb was almost entirely in the >5 µm size range and, indeed, may be associated with PM larger than 20 µm. (Sansalone et al., 2010) compared Pb-containing PM size distributions from Baton Rouge, LA, New Orleans, LA; Little Rock, AR; North Little Rock, AR; and Cincinnati, OH and found no common distribution pattern. Pb was associated with Cincinnati PM mainly in the <75 µm fractions, at Baton Rouge and Little Rock Pb mainly in the 75-425 µm PM

fractions, and at North Little Rock Pb predominantly in the >425 µm PM fractions. New Orleans Pb was almost uniformly distributed among the smaller size PM fractions. McKenzie et al. (2008) found that Pb was enriched in the finest PM (0.1-0.3 µm) in stormwater samples collected in California, particularly for storms that occurred during and after an extended dry period.

Guo et al. (2006a) investigated the effect of engineered partial exfiltration reactor (PER) systems on the partitioning and speciation of Pb in rainfall-runoff at the upstream end of an urban source area catchment that is part of the much larger urbanized and industrial Mill Creek watershed in Hamilton County, Ohio. The catchment is paved to a large extent with asphalt and is used for transportation. Guo et al. (2006a) investigated a catchment that drained toward a wide grassy area and found that Pb was mainly associated with dissolved organic matter (DOM) in the influent. The study suggested that interaction of the rainfall-runoff with the grassy area may have resulted in removal of PM-bound Pb. PM amount and size can also be influenced by the runoff surface. Guo et al. (2006a) found that Pb entering the engineered PER system was mainly in the dissolved fraction with ~76%.

There were several recent observations of a relationship between road traffic volume and runoff Pb concentration, although a clear relationship was not always observed. At a relatively clean location, Desta et al. (2007) studied highway runoff characteristics in Ireland and found that although as expected, Pb was strongly correlated with total suspended solids, no relationship between total suspended solids and rainfall, rain intensity, antecedent dry days or runoff event duration were observed. They concluded that runoff composition from site to site could be highly variable. Most other studies did find a relationship between traffic volume and Pb concentration. A California study of highway runoff by Kayhanian et al. (2007) reported that 70-80% Pb was in particulate form for both non-urban and urban highways, and that the concentration of Pb in runoff from low traffic flow (30,000-100,000 vehicles/day) urban highways was 50% higher than that from non-urban highways (total Pb mean = 16.6 µg/L). Additionally, the concentrations in runoff from high traffic flow (>100,000 vehicles/day) urban areas were five times higher than those from non-urban highways. Helmreich et al. (2010) characterized road runoff in Munich, Germany, with an average daily traffic load of 57,000 vehicles. The mean total Pb concentration, 56 µg/L (maximum value = 405 µg/L), lay in between the values for low traffic flow and high traffic flow runoff from urban areas in California, i.e., there was good agreement with Kayhanian et al. (2007). There was no detectable dissolved Pb, i.e., 100% in PM form. Seasonal effects of highway runoff have also been observed recently. Hallberg et al. (2007) found that summer particle-bound Pb concentrations in runoff water in Stockholm ranged from 1.37-47.5 µg/L while, in winter, the range was 1.06-~296 µg/L. There was a strong

correlation between Pb (and most other elements) and total suspended solids (R^2 = 0.89). Helmreich et al. (2010) also found higher metal concentrations during cold seasons in Stockholm but Pb concentrations increased only slightly during the snowmelt season. There was no change in the distribution of Pb between dissolved and PM forms for the rain and snowmelt periods. Runoff from urban snowmelt has been intensively investigated since the 2006 Pb AQCD was published. The relocation of snow means that the area receiving the snowmelt is not necessarily the same area that which received the snowfall. Magill and Sansalone (2010) also noted that plowed snowbanks alongside roadways form a temporary linear reservoir for traffic generated constituents such as metals and PM. Snowmelt concentrations of metals such as Pb can therefore be several orders of magnitude higher than those in rainfall runoff (Sansalone and Buchberger, 1996). The melt process usually occurs in a sequence: pavement melt, followed by roadside (impervious) and finally pervious area melt. As part of this sequence, rain-on-snow can transport high loads of PM-associated pollutants (Oberts, 2000). Westerlund and Viklander (2006) investigated differences in PM and Pb concentrations between rainfall events occurring during snowmelt and rain periods. Runoff events occurring during the snowmelt period (i.e., rain-on-snow) had about five times higher numbers of particles (in the size range 4 to 120 µm)/Liter of runoff. The first rain-on-snow event was characterized by an increase in the number of particles in the 4 to 25 µm size range. The rain-on-snow gave a "flush" through the snow but this was still not sufficient to transport the larger sized particles. Only the highest energy rain-on-snow events increased transport of PM across the entire size spectrum. There was no difference in particle size distributions between snowmelt and rain on snow events, although more was transported during snowmelt. Pb concentrations were most strongly associated with the smaller PM size fractions.

Overall, there was a significant difference between the melt period and the rain period in terms of concentrations, loads, transportation and association of heavy metals with particles in different size fractions (Westerlund and Viklander, 2006). Over a 4-year period, Magill and Sansalone (2010) analyzed the distribution of metal in snow plowed to the edge of roads in the Lake Tahoe catchment in Nevada, and concluded that metals including Pb were mainly associated with large PM (179-542 µm). The PM-associated metal could be readily separated from runoff water (e.g., in urban drainage systems), but there is potential for leaching of metals from the PM within storage basins (Ying and Sansalone, 2008). For adsorbed species that form outer sphere complexes, a decrease in adsorption and an increase in aqueous complexes for pollutant metals is a likely consequence of higher deicing salt concentrations. If metals form inner-sphere complexes directly coordinated to adsorbent surfaces, background deicing salt ions would have less impact. It is thought that physical and outer-sphere complexes predominate for coarse

PM, as was the case in Nevada, and so leaching would be likely to cause an increase in dissolved phase Pb concentrations.

Rural runoff has also been extensively studied since publication of the 2006 Pb AQCD (U.S. EPA, 2006b), including several recent publications on a forested watershed (Lake Plastic) in central Ontario (Landre et al., 2010, 2009; Watmough and Dillon, 2007) and nearby Kawagama Lake, Canada (Shotyk and Krachler, 2010). Results indicated that bulk deposition substantially decreased to 0.49 mg/m^2 in 2002 from 1.30-1.90 mg/m^2 in 1989-91. The upland soils retained >95% of the Pb in bulk deposition, i.e., leaching losses to stream water were small. The wetland area was, however, a net source of Pb with annual Pb concentrations in stream water ranging from 0.38 to 0.77 µg/L. Lake sediments were efficient sinks for atmospherically deposited Pb with 80-91% of the Pb input being retained. Up to 68% of the Pb entering the lake was derived from the terrestrial catchment. Overall, the watershed effectively retained atmospherically deposited Pb, but some Pb was then redistributed from the catchment to the lake sediments; and the Pb in the near-surface lake sediments reflected terrestrially transported soil material, rather Pb being deposited from the atmosphere. The highest concentrations of dissolved organic carbon (DOC), Fe and Pb in the wetland draining stream occurred in summer when Pb concentration frequently exceeded 1 µg/L (Landre et al., 2009).

Graham et al. (2006) observed two temporally separated mechanisms occurring during storm events in a rural organic rich upland catchment. At the beginning of an event, Pb was transported together with large particles in the >25 µm size range, but after several hours Pb was mainly transported with colloidal or DOM (<0.45 µm), and the remaining 30-40% of storm related Pb was transported in this form. This indicated that rapid overland flow rapidly transported Pb-PM into the receiving streams at the very beginning of the event, and this was followed within a few hours by transport of organic-colloidal Pb via near-surface throughflow. The authors used a conservative estimate of Pb removal, based on their observations that the catchment was continuing to act as a sink for Pb. These observations about the transport and fate of Pb agree well with those of Watmough and Dillon (2007) and Shotyk et al. (2010).

Soil type was also found to have a strong influence on runoff contributions. Dawson et al. (2010) found that for organic-rich soils Pb was mobilized from near-surface soils together with DOC, but for more minerogenic soils percolation of water allowed Pb bound to DOC to be retained in mineral horizons and combine with other groundwater sources. The resulting Pb in stream water had been had a more geogenic signature (Dawson et al., 2010). The findings of both Graham et al. (2006) and Dawson et al. (2010) were important because the provenance and transport mechanisms of Pb may greatly affect the net export to receiving waters, particularly since high concentrations of previously

deposited anthropogenic Pb are usually found in the near-surface sections of upland U.K. soils [e.g., (Farmer et al., 2005)].

In another study, Rothwell et al. (2007b) observed stormflow Pb concentrations in a peat catchment in Southern Pennines, U.K. almost three times higher than those reported by Graham et al. (2006) for northeastern Scotland. The generally high dissolved Pb were due to high soil Pb pools and high stream water DOC concentrations (Rothwell et al., 2007b). In a separate study, Rothwell et al. (2007a) showed that OM was the main vector for Pb transport in the fluvial system. Some seasonal variability was observed: declining Pb concentrations in autumn stormflow may indicate the exhaustion of DOC from the acrotelm (the hydrologically active upper layer of peat which is subject to a fluctuating water table and is generally aerobic) or a dilution effect from an increasing importance of overland flow.

Erosion of agricultural soils and the effects of different types of storm events on soil particle and Pb losses from these soils was characterized by Quinton and Catt (2007). A close link between metal concentration and the silt, or clay and organic content of stream sediments was consistent with enrichment of metals as a consequence of small erosion events. They also noted that short intense events could produce the same amount of sediment as longer low-intensity events. More intense events, however, could mobilize a wider range of particle sizes whereas low intensity events mobilized finer but more metal-rich material. Smaller events accounted for 52% of Pb losses from the agricultural soil.

The Tinto River in Spain drains one of the largest polymetallic massive sulfide regions in the world: the Iberian Pyrite Belt. Evaporitic sulfate salts, formed as a result of acid mine drainage processes, are considered to be a temporary sink for many heavy metals. Upon the arrival of rainfall, however, they rapidly dissolve, releasing acidity and contaminant metals into receiving waters. Thus rivers in semi-arid climate regions such as the Tinto River which alternate between long periods of drought and short but intense rainfall events, can experience quick acidification and increases in metal concentration. In a study of such events, Cánovas et al. (2010) found that while many element concentrations decreased during events, the concentrations of Fe, Cr, Pb and As increased. This was attributed to the redissolution and transformation of Fe oxyhydroxysulfates and/or desorption processes.

Dunlap et al. (2008) studied a large (>160,000 km^2) riparian system (the Sacramento River, CA) and showed that the present day flux of Pb into the river was dominated by Pb from historical anthropogenic sources, which included a mixture of high-ratio hydraulic Au mining-derived Pb and persistent historically-derived Pb from leaded on-road gasoline. Outside of the mining region, 57-67% Pb was derived from past on-road

gasoline emissions and 33-43% was from hydraulic Au mining sediment. Periods of high surface runoff mobilize additional fluxes of Pb from these two sources and carry them into the river.

Rothwell et al. (2007b) commented that although there have been substantial reductions in sulfur deposition to U.K. uplands over the last few decades (Fowler et al., 2005), anthropogenic acidification of upland waters is still possible if there is nitrogen leaching from the surrounding catchment and this may increase with nitrogen saturation (Curtis et al., 2005). Rothwell et al. (2007b) predicted that if an increase in surface water acidification is coupled with further increases in DOC export from organic-rich catchments, metal export from peatland systems will increase. The deterioration of peat soils by erosion is considered to be exacerbated by climatic change. Rothwell et al. (2010) used digital terrain analysis to model suspended Pb concentrations in contaminated peatland catchments. The peat soils of the Peak District are characterized by extensive eroding gullies and so they were combined in an empirical relationship between sediment-associated Pb concentrations and mean upslope gully depth with fine-resolution mapping of the gully areas. This model will enable prediction of metal contamination in receiving waters.

Klaminder et al. (2010) investigated the environmental recovery of sub-arctic lakes in response to reduced atmospheric deposition over the last few decades. They found that there had been no improvement in surface sediments and indeed the reduction in Pb contamination had been much less than the 90% reduction in emissions over the last four decades. The weak improvement in the $^{206}Pb/^{207}Pb$ ratio together with the Pb contaminant concentrations suggests that catchment export processes of previously-deposited atmospheric contaminants have had a considerable impact on the recent contaminant burden of sub-arctic lakes. In Arctic regions, soil export of contaminants to surface waters may dramatically increase in response to climate change if it triggers thawing of frozen soil layers. It is thought that thawing may generate accelerated soil erosion, altered hydrological flow paths, increased runoff and exposure of soluble compounds that had previously been in the frozen layers. At this stage, however, the links between catchment export and climate change have not yet been clearly established.

Coynel et al. (2007) also considered the effects of climate change on heavy metal transport. In this case, the scenario of flood-related transport of PM in the Garonne-Gironde fluvial-estuarine system was investigated. Export of suspended PM during a five-day flood in December 2003 was estimated at ~440,000 tons, accounting for ~75% of the annual suspended PM fluxes. Sediment remobilization accounted for ~42% of the total suspended particulate matter (SPM) flux during the flood event (~185,000 tons suspended PM) and accounted for 61% of the 51 tons Pb that was exported. Coynel et al.

(2007) postulate that flood hazards and transport of highly polluted sediment may increase as a result of climate change and/or other anthropogenic impacts (flood management, reservoir removal).

In heavily contaminated catchments [e.g., that of the Litavka River, Czech Republic (Zak et al., 2009)], the flux of heavy metals to the river during storm events can be substantial. Even during a minor 4-day event, 2,954 kg of Pb was transported, and the majority was associated with suspended PM. For the Adour River in a mountainous area of France, Pb pollution predominantly originated from mining activities, and Point et al. (2007) showed that 75% of annual soil fluxes into the river were transported in 30-40 days.

The consequences of flood management (dam flushing) practices on suspended PM and heavy metal fluxes in a fluvial-estuarine system (Garonne-Gironde, France) were considered by Coynel et al. (2007). Dam flushing enhanced mobilization of up to 30-year-old polluted sediment from reservoir lakes. Sediment remobilization accounted for ~42% of the total suspended PM fluxes during the flood and strongly contributed to PM-bound metal transport (61% for Pb). They concluded that flood management will need to be taken into consideration in future models for erosion and pollutant transport.

Bur et al. (2009) investigated the associations of Pb in stream-bed sediments of the French Gascony region. They found that Pb enrichment in stream sediments was positively correlated with catchment cover and increasing organic content whereas Pb concentration was strongly linked with Fe-oxide content in cultivated catchments. For the low-OM, anthropogenic Pb was associated with carbonates and Fe-oxides (preferentially, the amorphous fraction). Fe-oxides became the most efficient anthropogenic Pb trapping component as soon as the carbonate content is reduced. They noted, however, that OM was always weakly involved. N'Guessan et al. (2009) also studied trace elements in stream-bed sediments of the French Gascony region. They used enrichment factors to show that only ~20-22% of Pb was from anthropogenic sources with the remainder originating from natural weathering processes.

Overall, research results from the last several years have greatly expanded the extent of the knowledge concerning Pb from runoff. Substantial Pb input to estuarine and marine ecosystems has been well documented. More detail concerning the origin of Pb from roof runoff has led to the conclusion that roof flashing could be especially important. Research on road runoff has provided valuable insight into PM size and composition, indicating that size distributions for Pb-containing PM in runoff water varies from study to study and from location to location. Recent studies confirmed the "first flush" effect, releasing more Pb at the beginning of rainfall than subsequently, and documented size distributions of Pb-containing PM also vary considerably when water from the first flush is isolated. Influence of road traffic volume on runoff has also been more fully documented in recent

years. The role of urban snowmelt and rain-on-snow events is also better understood, and it has been observed that greater runoff occurs from snowmelt and in rain-on-snow events than when snow is not present, and that metals, including Pb, are often associated with coarse PM under these circumstances. Runoff in rural areas is strongly controlled by soil type and the presence of vegetation, with less runoff and greater retention in mineral soils or when grass is present, and more runoff for soils high in OM. Runoff also follows a two-step process of transport of larger particles at the beginning of an event, followed within hours by transport of finer colloidal material. Some initial research on the effects of climate change on runoff has focused on documenting the association between increased runoff and more intense rain events and greater thawing. Overall, recent research has provided greater detail on amounts, particle size distributions, composition, and important processes involving Pb transport, and the understanding of Pb runoff has become more complete since publication of the 2006 Pb AQCD (U.S. EPA, 2006b).

3.3.3 Soil

The 2006 Pb AQCD (U.S. EPA, 2006b) summarized that Pb has a relatively long retention time in the organic soil horizon, although its movement through the soil column also suggests potential for contamination of groundwater. Leaching was consistently observed to be a slower process for Pb than for other contaminants because Pb was only weakly soluble in pore water, but anthropogenic Pb is more available for leaching than natural Pb in soil. Pb can bind to many different surfaces and Pb sorption capacity is influenced by hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, animal holes, and geochemical reactions. As a result of Pb binding to soil components, leaching is retarded by partitioning to soils, which is not only influenced by sorption capacity, but leaching also increases with proximity to source, increasing pH, and increasing metal concentrations. Leaching is also strongly influenced by pore water flow rates, with more complete sorption contributing to slower leaching at lighter flows. Leaching rates are especially high in soils with a high Cl content, but typically the most labile Pb fraction is adsorbed to colloidal particles that include OM, clay, and carbonates. Transport through soils is enhanced by increasing amount of colloidal suspensions, increasing colloidal surface charge, increasing organic content of colloids, increasing colloidal macroporosity, and decreasing colloidal size. Acidity and alkalinity have a more complex influence, with sorption maximized at neutral pH between pH = 5 and pH = 8.2, and greater mobility at higher and lower pH. High Pb levels have been observed in leachates from some contaminated soils, but this effect appears to be pH dependent. In several studies of contaminated soils a substantial

fraction of Pb was associated with Mn and Fe oxides or carbonate. Influence of soil chemistry on Pb effects in ecosystems is described in Section 7.3.2.

3.3.3.1 Deposition of Pb onto Soil from Air

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), a considerable amount of Pb has been deposited from air onto soils in urban areas and near stationary sources and mines. Removal and translocation of Pb in soil is an ongoing process.

High Pb soil concentrations were observed near stationary sources such as smelters and battery disposal operations, and soil Pb concentrations decreased rapidly with distance from the source. Several recent studies continue to document high concentrations of Pb in soil. A study of soil Pb concentrations in Queensland, Australia described atmospheric transport and deposition of Pb in soils (due to ongoing emissions from nearby mining [which began in 1924] and smelting [which began in 1931] activities) are continuing to impact the urban environment, resulting in elevated soil Pb concentrations at urban property sites within 2 km of the mines (Taylor et al., 2010). Similarly, sediment cores from four remote Canadian Shield headwater lakes located along a transect extending 300 km from a non-ferrous metal smelter generated useful information about distance of Pb transport from the smelter prior to deposition (Gallon et al., 2006). Shotyk and Krachler (2010) postulated that long-range transport of Pb from a smelter at Rouyn-Noranda may still contribute to deposition on these lakes. Recent measurements of deposition fluxes to soil in rural and remote areas have ranged from approximately 0.5 $mg/m^2 \cdot yr$ to about 3 $mg/m^2 \cdot yr$ with fair agreement between locations in Canada, Scandinavia, and Scotland and showed a substantial decrease compared to when leaded on-road gasoline was in widespread use (Shotbolt et al., 2008; Watmough and Dillon, 2007; Fowler et al., 2006; Graham et al., 2006).

There has been considerable interest in the response of soils to the decreasing aerosol Pb concentrations and Pb deposition rates that have been recorded in recent years. Kaste et al. (2006) resampled soils at 26 locations in the Northeast U.S. (during a 2001-2002 survey of soil sites originally sampled in 1980), and found no significant change in the amount of Pb in the O-horizon at high altitude sites, suggested to be related to reduced microbial activity at altitude. However, the amount of Pb in the O-horizon had decreased at some locations in the southern part of the survey region (Connecticut, New York, Pennsylvania), where the forest soils have typically thinner O-horizons, the reasons for which are discussed further in Section 3.3.3.2. Relatively high Pb concentrations were also found in Japan, especially above 600 meters altitude compared with lower altitude soils sampled during the study (Takamatsu et al., 2010).

Further support for the use of mosses as bioindicators or monitors for atmospheric Pb inputs to peat bogs have recently been published by Kempter et al. (2010) who found that high moss productivity did not cause a dilution of Pb concentrations in peat bogs. They also found that productive plants were able to accumulate particles from the air and that rates of net Pb accumulation by the mosses were in excellent agreement with the atmospheric fluxes obtained by direct atmospheric measurements at nearby monitoring stations. In addition, Bindler et al. (2008) used Pb isotopes to compare the distribution of Pb in the forest soils with that of lake sediments where no "plant pumping" processes could be invoked, and used Pb isotope ratios to demonstrate that observations were consistent with anthropogenic Pb deposition to the soils rather than intermixing of natural Pb from underlying mineral soil horizons.

Overall, recent studies provided deposition data that was consistent with deposition fluxes reported in the 2006 Pb AQCD (U.S. EPA, 2006b), and demonstrated consistently that Pb deposition to soils has decreased since the phase-out of leaded on-road gasoline. Follow-up studies in several locations at high altitude indicated little change in soil Pb concentrations since the phase-out of leaded on-road gasoline, although reductions in surface soil Pb concentrations have been documented in some areas.

3.3.3.2 Sequestration of Pb from Water to Soil

The 2006 Pb AQCD described Pb as being more strongly retained in soil than other metals because of its weak solubility in pore water, but that anthropogenic Pb was more available for leaching than natural Pb (U.S. EPA, 2006b). It also described a complex variety of factors that influence Pb retention, including hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, geochemical reactions, colloid amounts, colloidal surface charge, and pH.

Recent research in this area has provided more insight into the details of the Pb sequestration process. Importance of leaf litter was further investigated, and it was observed that the absolute Pb content can be substantial because rain events cause splashing of the leaf litter with soil thus placing the litter in direct contact with soil metals. The resulting increase in leaf litter metal concentrations suggests that the litter can act as a temporary sink for metals from the soil around and below leaves on the ground. The low solubility of Pb in the leaf litter indicates that the Pb is tightly bound to the decomposing litter, making the decomposing leaves act as an efficient metal storage pool (Scheid et al., 2009). Differences between throughfall (i.e., water depositing onto the soil following collection on leaves) and litterfall (i.e., deposition of leaves, bark, and other vegetative debris onto soil) in forested areas have been investigated in forested

areas, and the combined input of Pb to the forest floor from throughfall and litterfall was approximately twice that measured in bulk deposition (Landre et al., 2010). The difference was attributed to a substantial contribution from internal forest cycling and indicates that bulk deposition collectors may underestimate the amount of Pb reaching the forest floor by about 50% (Landre et al., 2010).

New research has also provided details about the complexity of Pb sequestration during soil OM decomposition. Schroth et al. (2008) investigated Pb sequestration in the surface layer of forest soils and the transformation of Pb speciation during soil OM decomposition. The pH range for forest floor soils in the Northeast U.S. is typically 3.5-5 and, under these conditions, dissolved Pb would adsorb strongly to soluble OM and to Fe/Al/Mn oxides and oxyhydroxides. It had been thought that the high affinity of Pb for organic ligands meant that sequestered atmospheric Pb would be preferentially bound to soluble OM. As a consequence, decomposition of OM would lead to Pb migration to the underlying mineral layers where it would be precipitated with the dissolved OC or adsorbed to pedogenic mineral phases. However, recent research has revealed a more complicated picture of gasoline-derived Pb associations in the forest floor. More recent research indicates that, as decomposition progresses, Pb and Fe become more concentrated in “hotspots” and Pb likely becomes increasingly distributed on surfaces associated with Fe and Mn (and to some extent Ca). It was postulated that Pb was initially bound to labile organic but, following decomposition, the Pb was adsorbed at reactive sites on pedogenic mineral phases (Schroth et al., 2008). Differences in litter types were also reported, with more rapid decomposition of OM in deciduous litter mobilizing more Pb initially bound to labile OM than coniferous litter, and producing more pedogenic minerals that could readily sequester the released Pb (Schroth et al., 2008). In the next stage of the study, the speciation of Pb in the O-horizon soils of Northern Hardwood, Norway spruce and red pine forest soils were compared. In general there was good agreement between the Pb speciation results for the soils and those for the laboratory decomposition experiments. Specifically, for the Northern Hardwood forest soil, a little more than 60% of the Pb was bound to soil organic matter (SOM) and this percentage increased to ~70% and ~80% for the Norway spruce and red pine soils, respectively. In all three cases, however, most of the remainder of the Pb was bound to ferrihydrite rather than to birnessite. This was not considered to be surprising because of the well-known leaching and cycling behavior of Mn that would be expected in the natural system. Thus the prevalence of Mn phases in the field based samples would be lessened (Schroth et al., 2008).

More generally, other studies have observed Pb sorption to Mn and Fe phases in soils. For example, Boonfueng et al. (2006) investigated Pb sequestration on Mn oxide-coated montmorillonite. Pb formed bidentate corner-sharing complexes. It was found that Pb

sorption to MnO_2 occurred even when MnO_2 was present as a coating on other minerals, e.g., montmorillonite. Although their importance in the near-surface phases has clearly been demonstrated by Schroth et al. (2008), ferrihydrite surfaces may not be a long-term sink for Pb since reductive dissolution of this Fe(III) phase may release the surface-bound Pb into the soil solution. Sturm et al. (2008) explored the fate of Pb during dissimilatory Fe reduction. Pb was indeed released but was then incorporated into less reactive phases. These phases could not, however, be identified. Even so, it was asserted that Pb should be largely immobile under Fe-reducing conditions due to its incorporation into refractory secondary minerals.

Kaste et al. (2006) found that Pb species currently in the soil O-horizons of the Northeast U.S. differed considerably from those that were originally deposited from fossil fuel combustion (including on-road gasoline). $PbSO_4$ was considered to be the main form of Pb that had been delivered from the atmosphere to the surface of the Earth and it was postulated that the presence of sulfate may have facilitated the adsorption of Pb to colloidal Fe phases within the organic-rich horizons.

Altogether, these new results enhance the understanding of Pb sequestration in forest soils. First, the role of leaf litter as a major Pb reservoir is better understood. Second, the effect of decomposition on Pb distribution and sequestration on minerals during OM decomposition has been further characterized, and finally, the relative importance of Mn and Fe in sequestration is better understood.

Recent research also addressed roadsides soils. Jensen et al. (2006) found that Pb was retained by an organic-rich blackish deposit with a high OM content and elevated soil Pb concentrations, originating from total suspended solids in road runoff and from aerial deposition. Hossain et al. (2007) observed that after long dry periods, OM oxidation may potentially result in the release of Pb. Microbial activity may also breakdown OM and have similar consequences (i.e., Pb release). Bouvet et al. (2007) investigated the effect of pH on retention of Pb by roadside soils where municipal solid waste incineration (MSWI) bottom ash had been used for road construction. They found that the Pb that had leached from the road construction materials was retained by the proximal soils under the prevailing environmental conditions (at pH = 7, <2% was released, but at pH = 4, slightly more Pb (4-47%) was released) and the authors speculated that the phase from which Pb had been released may have been $Pb(CO_3)_2(OH)_2$, indicating that sequestration of Pb via formation of oxycarbonate minerals is only effective at near-neutral to alkaline pH values (Figure 3-11 in Section 3.3.3.3).

Other recent research on Pb sequestration focused on microbial impacts and soil amendments. There have been few if any previous observations of microbial sequestration of Pb in soil. Perdrial et al. (2008) observed bacterial Pb sequestration and

proposed a mechanism of Pb complexation by polyphosphate. They also postulated that bacterial transport of Pb could be important in sub-surface soil environments. Wu et al. (2006) also and concluded that Pb adsorption to the bacterial cell walls may be important with respect to Pb transport in soils. This new area of research suggests that bacteria can play an important role in both sequestration and transport of Pb. Phosphate addition to immobilize Pb-contaminated soils has often been used to immobilize Pb in situ through the formation of Pb phosphate minerals such as chloropyromorphite. Recent research investigated factors affecting the long-term stability of such products, which depends on the equilibrium solubility and the dissolution rate of the mineral, trace impurities, such as $Pb(OH)_2$, the presence of complexing agents, and pH (Xie and Giammar, 2007). Overall, in agreement with the 2006 Pb AQCD (U.S. EPA, 2006b), the addition of phosphate can enhance immobilization of Pb under certain conditions in the field but may cause desorption and mobilization of anionic species of As, Cr and Se.

3.3.3.3 Movement of Pb within the Soil Column

The 2006 Pb AQCD summarized studies that demonstrated that Pb has a long retention time in the organic soil horizon, it also has some capacity to leach through the soil column and contaminate groundwater more than other contaminants do, because Pb is only weakly soluble in pore water (U.S. EPA, 2006b). The fate of any metal transport in soil is in response to a complex set of parameters including soil texture, mineralogy, pH and redox potential, hydraulic conductivity, abundance of OM and oxyhydroxides of Al, Fe, and Mn, in addition to climate, situation and nature of the parent material. As a consequence, it is impossible to make general conclusions about the final fate of anthropogenic Pb in soils. Indeed, Shotyk and LeRoux (2005) contend that the fate of Pb in soils may have to be evaluated on the basis of soil type. Some generalizations are, however, possible: Pb migration is likely to be greater under acidic soil conditions (Shotyk and Le Roux, 2005). In this respect, it would be expected that there should be considerable mobility of Pb in the surface layers of certain types of forest soils. This section reviews recent research on movement of Pb through soil types by first focusing on forest soils, followed by a broader treatment of a more diverse range of soils.

Forest Soils and Wetlands

Several studies confirmed the slow downward movement of Pb within the soil column. Kaste et al. (2006) found that the amount of Pb in O-horizon soils had remained constant at 15 of 26 sites in remote forested areas of the Northeast U.S. that had been re-sampled after a 21-year time period had elapsed, but that measured soil Pb concentrations were

lower than predicted concentrations from total deposition, strongly suggesting that the O-horizon had not retained all of the atmospheric Pb, and that a proportion of the atmospheric deposition must have leached into the underlying mineral layers. At some sites, mainly those at the southern latitudes and lower altitude sites, the proportion of Pb that had been leached downward from the O-horizon was quite considerable. Relative retention of Pb was influenced by the rate of OM decomposition, depth of soil O-horizon, and pH. For soils where Pb was strongly retained by the O-horizon, a relationship between Pb and Fe-rich phase was observed, but Pb was also significantly correlated with other metals. XANES data suggested a possible interaction with an amorphous Fe oxide, but spectra were not entirely explained by Fe and oxygen and an additional spectral feature suggested the presence of a sulfur (S) or phosphorus (P) atom, which could result if OM functional groups were binding to Pb. Kaste et al. (2006) concluded that a substantial fraction of Pb was associated with amorphous Fe-hydroxides. The strong binding of Pb coupled with the low solubility of Fe phases under oxic conditions, helped to explain the relatively long residence time of gasoline-derived Pb in forest floors which had thick O-horizons and were well-drained. In the situations where Pb was leached downward to a large extent, mobility was likely governed by OM decomposition and colloidal transport of Pb associated with colloidal Fe and OM.

Klaminder et al. (2006b) also considered the transfer of Pb from the O-horizon to the underlying mineral horizons (including the C-horizon). They concluded that atmospheric pollution-derived Pb migrated at a rate about 10-1,000 times slower than water. They assumed that Pb was mainly transported by dissolved OM and so the mean-residence-time of Pb in the O-horizon depended on OM transport and turnover. The retardation rate was a reflection of the slow mineralization and slow downward transport rates of organic-Pb complexes, due to sorption and desorption reactions involving mineral surfaces.

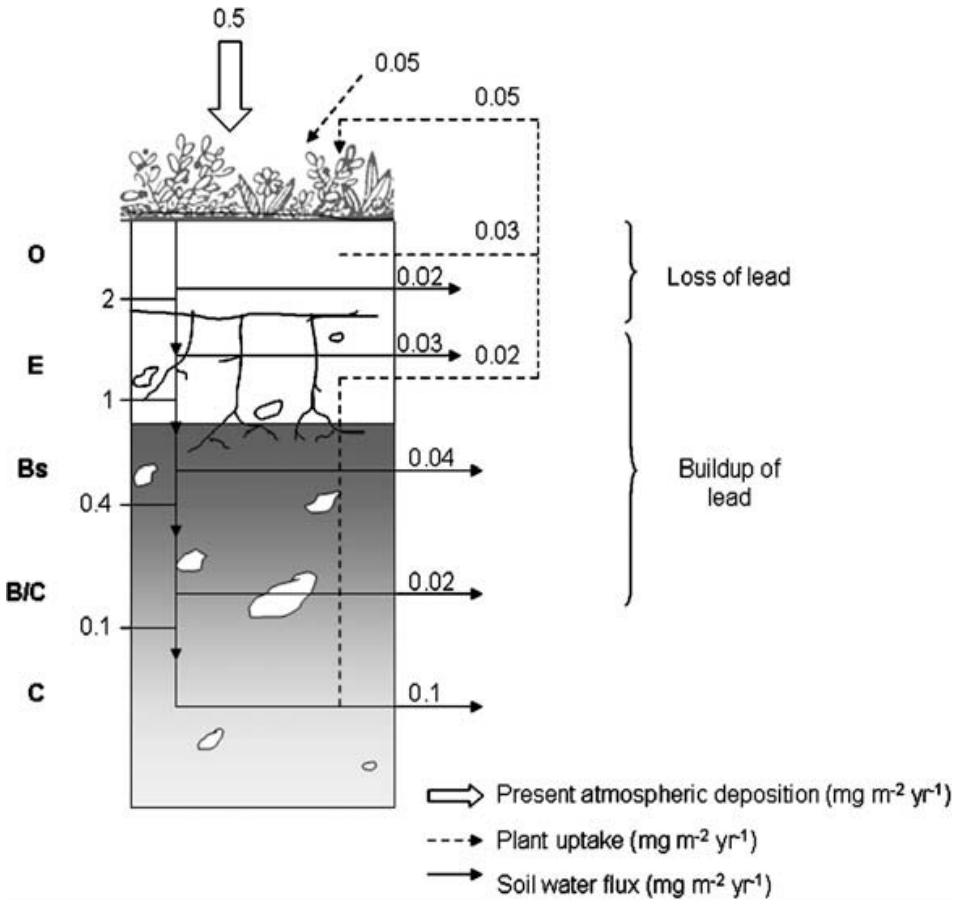
In a study involving stable Pb isotopes, Bindler et al. (2008) showed that Pb with a different isotopic composition could be detected in the soil down to a depth of at least 30 cm and sometimes down to 80 cm in Swedish soils. In comparison, in North American podzols, pollution Pb is typically only identified to a depth of 10-20 cm (even with the aid of isotopes). This difference is attributed to the longer history of metal pollution in Europe (as has been traced using lake sediments).

Several research groups have attempted to determine the mean residence time of Pb in the O-horizon of forest soils. Klaminder et al. (2006a) used three independent methods to estimate a mean residence time of about 250 years for Pb in the O-horizon of boreal forests in Sweden, indicating that deposited atmospheric Pb pollution is stored in the near-surface layers for a considerable period and, consequently, will respond only slowly to the reduction in atmospheric inputs. It should be noted, however, the OM in the upper

parts of the O-horizon is continually being replaced by fresh litter and the mean residence time of Pb in these horizons is only 1-2 years. Thus, the uppermost layer will respond more quickly than the rest of the O-horizon to the decreases in Pb inputs.

Klaminder et al. (2008a) considered the biogeochemical behavior of atmospherically derived Pb in boreal forest soils in Sweden (Figure 3-11). The estimated annual losses via percolating soil water were ~2 mg/m^2·yr (Klaminder et al., 2008a) and so the annual loss, assumed to be from the mor layer, was greater than the atmospheric input of ~0.5 mg/m^2·yr. The upward transport of Pb did not compensate for the losses either. In contrast, the amount of Pb being stored in the mineral soil layers was increasing. The mean residence time of Pb in the mor layer was estimated to be ~300 years, in reasonable agreement with their earlier work (Klaminder et al., 2006a). These values were greater than the values of 2-150 years determined for U.S. forest soils, e.g., (Watmough et al., 2004; Kaste et al., 2003) but the difference was attributed to the lower decomposition rates of OM within the northern boreal forests of Sweden. They concluded that more research was needed to determine the processes occurring within the mor layer that control the release of Pb from this horizon.

Klaminder et al. (2008b) investigated in more detail the distribution and isotopic signature of Pb persisted within the O-horizon (mor layer) of boreal forest soils. They found that the mor layer preserved a record of past Pb emissions from a nearby smelter. Minimal animal burrowing activity and low leaching rates observed at the sampling location were important factors contributing to the preservation of this record. They concluded that temporal changes in atmospheric fallout in addition to adsorption processes need to be considered when interpreting Pb concentrations changes within the mor layer.



Notes The atmospheric deposition rate is from (Klaminder et al., 2006a), the plant uptake rates from (Klaminder et al., 2005) and estimated soil-water fluxes from (Klaminder et al., 2006b).

Figure 3-11 Schematic model summarizing the estimated flux of Pb within a typical podzol profile from northern Sweden using data from Klaminder et al. (2006a).

Significantly higher O-horizon Pb concentrations have been observed in coniferous than deciduous forest soils (McGee et al., 2007). Steinnes et al. (2005) noted evidence for downward migration of Pb from the O-horizon to the E-horizon of most soils and in some cases the upper B-horizon. They found that the downward transport of Pb differed considerably between the sites, e.g., from almost no anthropogenic Pb in the B-horizon at some sites to ~70% at other sites. The greater downwards transport in some locations was attributed to climatic variations, with more extensive leaching and possibly a greater turnover of OM at sites where higher mean annual temperatures were experienced. Higher atmospheric deposition of acidifying substances in these locations was considered the most important factor in Pb transport, causing release of Pb from exchange sites in the humus layer and promoting downward leaching.

Seasonal variation in Pb mobility has also been observed in forest soil. Other research indicated that Pb concentrations correlated with DOC concentrations in the soil solution from the O-horizon, and were lower during late winter and spring compared with summer months (Landre et al., 2009). The degradation of OM in the O-horizon produced high DOC concentrations in the soil solution. It was also shown that Pb was associated with the DOC, and concluded that DOC production is a primary factor enhancing metal mobility in this horizon. In the underlying mineral horizons, DOC concentrations declined due to adsorption and cation exchange processes. The B-horizon retained most of the DOC leached from the O-horizon and it has also been observed that Pb is similarly retained.

Non-forested Soils

In contrast with forest soils, most non-forested soils are less acidic and so most studies of Pb behavior in non-forested soils have focused on Pb immobility. However, there are acid soils in some locations that are not forested. For these soils, as for forest soils, Pb mobility is weak but correlated with OM. For example, Schwab et al. (2008) observed that low molecular weight organic acids added to soil enhanced Pb movement only slightly. Citric acid and tartaric acid enhanced Pb transport to the greatest degree but the extent of mobilization was only slightly higher than that attained using deionized water even at high concentrations. While the formation of stable solution complexes and more acidic conditions favored mobilization of Zn and Cd, Pb remained strongly sorbed to soil particles and so the presence of complexing agents and low pH (2.8-3.8) did not substantially enhance Pb mobility. Similarly, limited penetration and leaching was observed in an extremely complex temperate soil profile, with highest concentrations of Pb (~80 mg/kg) found in the top 0-5 cm section of soil. For this uppermost soil section, there was a strong correlation between Pb concentration and OC content, both for the total soil fraction and the acid-extractable fraction. The Pb migration rate was calculated to be 0.01 cm/yr and it was estimated that Pb would be retained in the soil column for 20,000 years, with no evidence of rapid movement of anthropogenic Pb from the top 0-5 cm soil section into the soil profile Kylander et al. (2008).

Other recent studies also reported strong retention in non-forest soils and enhanced mobility of Fe and OM colloids. Pb was strongly retained on acidic Mediterranean soil columns, and association of Pb with the exchangeable OM and crystalline Fe oxide fractions appeared to favor mobility, while Pb association with Mn oxides and amorphous Fe oxides was linked with semi-irreversible retention of Pb in the solid phase (Garrido et al., 2008). In another study of Pb mobility within Mediterranean soils, Pb infiltration velocity was measured to be 0.005 meter/year (Erel, 1998). The authors attributed Pb movement within the soil column to advection and concluded that the soil

profile of Pb is similar to the anthropogenic air Pb emissions trend. Pedrot et al. (2008) studied colloid-mediated trace element release at the soil/water interface and showed that Pb was mobilized by Fe nanoparticles that were bound to humic acids.

Soil pH value is probably the single most important factor affecting solubility, mobility and phytoavailability but reducing conditions also results in increased Pb mobility, with the release of Pb into an anoxic soil solution due to the combined effect of Fe(III) reductive dissolution and dissolved OM release. Dissolved OM is more important than Fe oxyhydroxides in determining Pb mobility. Under oxic conditions, Fe-Mn-hydroxides often play an important role in the sorption of Pb to the solid phase soil (Schulz-Zunkel and Krueger, 2009). In an agricultural soil, fate of Pb in soils is related to agricultural management. Although Pb was found to be strongly sorbed to the soil, downward migration was observed and the movement of Pb to deeper soils was due to the soil mixing activities of earthworms (Fernandez et al., 2007). Thus in relatively unpolluted non-forested soils, as in forested soils, colloidal Fe and OM, pH, and biophysical transport all enhance Pb mobility in soil. Pb transport in more highly contaminated soils has also been the subject of recent research. In a vegetated roadside soil, Pb was leached from the upper 50 cm of the soil even though the pH was 7.2. Pb was transported on mobile particles and colloids in the soil solution. Some of the colloids may have formed from OM produced by roots and decaying shoots. The transport process was enhanced by preferential flow triggered by intense rainfall events. This study suggested that the value of the effective sorption coefficient estimated under dynamic conditions was unrelated to values measured in conventional batch studies. This indicates that the use of batch studies to derive input values for sorption coefficients in transport models requires caution. It was concluded that the primary control of Pb transport in the long term was the degree of preferential flow in the system (Roulier et al., 2008b).

Other studies also noted similarly low Pb mobility, but with substantial variation between soil types and locations. A decline in O-horizon Pb concentrations and Pb accumulation in mineral horizons was also observed for forest soils by Watmough and Dillon (2007), but did not hold for nearby wetland areas from which a large amount of DOC is exported, with approximately 10 times more Pb being associated with a given amount of DOC in the leachate from the LFH-horizon of the wetland soil than with the DOC in the stream water draining the wetland. This may reflect greater retention of Pb by the wetland and/or a change in structure of DOC leading to a change in complexing capacity possibly because of changes in pH or competition with Al and Fe.

Williams et al. (2006) characterized Pb speciation in a mine waste-derived fertilizer, ironite. It was thought that PbS would be the main form of Pb, but instead was the predominant form was $PbSO_4$, which may move more easily through soil and enter

proximal waters. In contrast, Courtin-Nomade et al. (2008) showed that Pb was incorporated into barite rather than goethite in waste rock pile materials. The high-stability phase formed was an anglesite-barite solid solution.

In weathering flotation residues of a Zn-Pb sulfide mine, more Pb was mobile in weathered topsoil than in the unweathered subsoil (Schuwirth et al., 2007). The topsoil had a very high OM content and the Pb enrichment was attributed to an interaction with soil OM. Overall, the results contrast strongly with most other studies but the interpretation was supported by the sequential extraction results which showed that there was a very large exchangeable Pb component in these surface soils. Scheetz and Rimstidt (2009) characterized shooting range soils in Jefferson National Forest, VA, in which the metallic Pb shot rapidly became corroded and developed a coating of hydrocerussite, which dissolved at the pH values of 8-9; see Figure 3-12, which shows an Eh-pH diagram indicating the solubility, equilibrium, and stability of these corroded Pb molecules in terms of the activity of hydrogen ions (pH) versus the activity of electrons (Eh [in volts]). The solubilized Pb was largely re-adsorbed by the Fe and Mn oxides and carbonate soil fractions. The minimum solubility of hydrocerussite lies in the pH range 8-9 but solubility increases by several orders of magnitude at pH below 6 (Scheetz and Rimstidt, 2009).

Figure 3-12 Eh-pH diagram for Pb in shooting range soils, Jefferson National Forest, VA.

Rooney et al. (2007) also investigated the controls on Pb solubility in soils contaminated with Pb shot. Again, corrosion crusts were found to develop on Pb pellets. The concentrations of Pb in the soil solution were, however, much lower than if they were controlled by the solubility of the dominant crustal Pb compounds (mainly hydrocerussite). Instead it was suggested that the concentrations were being controlled by sorption of Pb by the soil solid phase. The pH range in this study was 4.5-6.5 and so again dissolution of hydrocerussite would be expected. Sorption to solid phases in the soil is also consistent with the findings of Scheetz and Rimstidt (2009). Overall, in contrast to less polluted forested and non-forested soils, considerable mobility was often, but not always observed in soils near roadways and mines and on shooting ranges, with colloid transport and soil pH playing an important role in Pb mobility. Although there have been steep declines in Pb deposition, surface soils in have been slow to recover (Bindler et al., 2008; Kaste et al., 2006). As was concluded in the 2006 Pb AQCD (U.S. EPA, 2006b), soils continue to act as a predominant sink for Pb.

While in some studies the flux of Pb, from the soil through aquatic ecosystems to lakes has peaked and declined. In other studies, no recovery of lake sediments in response to emission reductions was observed (Norton, 2007). For example, Klaminder et al. (2010) has shown that the Pb concentrations in sub-Arctic lake sediments remain unchanged in recent years, with the lack of recovery linked to the effects of soil warming, which affect Pb-OM transport from soil to the receiving lake systems. Shotyk and Krachler (2010) also reported a disconnect between atmospheric deposition and recent changes in Pb concentration and isotope ratios in the lake sediments. Simulations of future metal behavior suggest that the more strongly sorbing metals such as Pb will respond to changes in metal inputs or acidification status only over centuries to millennia (Tipping et al., 2006).

Overall, recent research confirms the generally low mobility of Pb in soil. This limited mobility is strongly dependent on both colloid amount and composition, as well as pH, and may be greater in some contaminated soils. Mobility is so low that soils continue to act as a sink for atmospheric Pb even though atmospheric Pb concentrations peaked several decades ago.

3.4 Monitoring of Ambient Pb

3.4.1 Measurement Techniques

3.4.1.1 Sample Collection

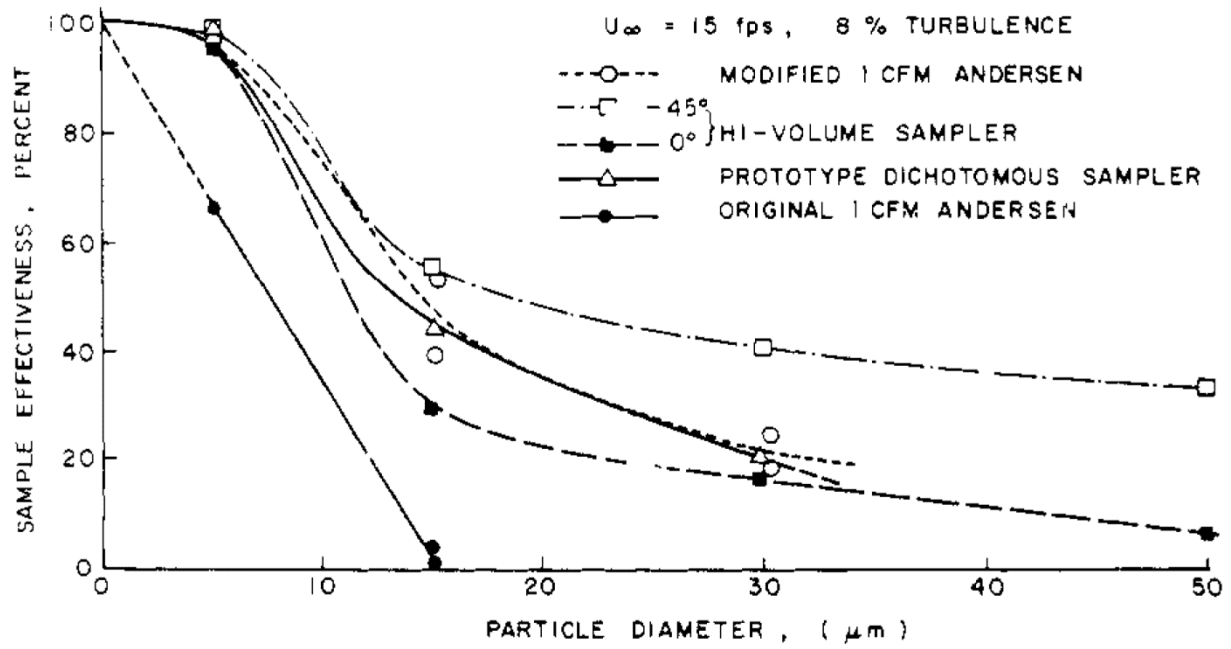
Federal Reference Methods

The indicator for the Pb NAAQS is Pb in total suspended particles (Pb-TSP) (73 FR 66964). In order to be used in regulatory decisions judging attainment of the Pb NAAQS, ambient Pb concentration data must be obtained for this indicator using either the Federal Reference Method (FRM) or a Federal Equivalent Method (FEM) defined for this purpose. Accordingly, for enforcement of the air quality standards set forth under the Clean Air Act, EPA has established provisions in the Code of Federal Regulations under which analytical methods can be designated as FRM or FEM. Measurements for determinations of NAAQS compliance must be made with FRMs or FEMs. FRMs and FEMs for the Pb NAAQS exist for both sample collection and sample analysis.

There are two FRMs for sample collection in the Pb NAAQS monitoring network (described in Section 3.4.2 below): (1) Reference Method for the Determination of Lead in Suspended Particulate Matter Collected From Ambient Air (40 CFR part 50 Appendix G), and (2) Reference Method for the Determination of Lead in Particulate Matter as PM_{10} Collected From Ambient Air (40 CFR part 50, Appendix G). The Pb-TSP FRM sample collection method is required for all source-oriented NAAQS monitors, and the FRM for Pb-PM_{10} is accepted for Pb NAAQS monitoring at non-source-oriented monitors in specified situations.

The Pb-TSP FRM sample collection method specifies use of a high-volume TSP sampler that meets specified design criteria (40 CFR part 50 Appendix B). Ambient airborne PM is collected on a glass fiber filter for 24 hours using a high volume air sampler. It has long been recognized that there is notable variability in high-volume TSP sample measurements associated with the effects of wind speed and wind direction on collection efficiency. This variability is predominantly associated with the capture efficiency for particles larger than 10 µm, but the sampler's size selective performance is known to be affected by wind speed and direction. For example, at a simulated wind speed of 4.6

meters/second, a directional difference of 45 degrees can result in a nearly two-fold difference in 15 µm particle collection efficiency and a nearly five-fold difference in 50 µm particle collection efficiency (Wedding et al., 1977). Effective D_{50} (size at 50% efficiency) was observed to decrease from 50 µm at a 2 km/h wind speed to 22 µm at 24 km/h (Rodes and Evans, 1985). Figure 3-13 illustrates the effect of sampler orientation on collection efficiency as a function of particle size.



Different TSP sampler types: (1) Modified Andersen Sampler [open circles]; (2) Hi-volume Sampler (for different incident wind direction (45° [open squares], 0° [closed squares); (3) Prototype 15 µm Cutpoint Dichotomous Sampler [open triangles]; and (4) Original Andersen Sampler [closed circles].

Source: Reprinted with permission of the American Chemical Society (Wedding et al., 1977)

Figure 3-13 Comparison of particle collection efficiency among different TSP sampler types.

Some existing commercially available sampler inlets are designed to collect particles larger than 10 µm with greater than 50% efficiency (Kenny et al., 2005), and these inlets can be tested as potential replacements for TSP sampling. Efficient collection of particles much larger than 10 µm is considerably more challenging because their greater inertia and higher settling velocities hinder their efficient intake by samplers. The sampling difficulties and the long history of research to develop adequate sampling technology for large particles have been thoroughly reviewed (Garland and Nicholson, 1991). High intake velocities and large inlet openings are necessary to minimize sampling bias for

sampling ultra-coarse particles. At this time, no alternative to the FRM TSP sampler has been identified that has been adequately characterized. As such, there is a continued need to assess the feasibility of a revised TSP sampler design with improved control on collection efficiency over a wider range of particle sizes, including ultra-coarse particles (which are not captured with PM_{10} samplers).

The spatial scale for which ambient air Pb samples are representative varies depending on particle sizes present, as discussed further in Section 3.5.3. Concentrations of particles larger than 10 µm are likely to be very spatially and temporally heterogeneous, with higher concentrations in the vicinity of their emissions sources. Under typical conditions, $PM_{10-2.5}$ particles travel much shorter distances before settling out than finer particles (U.S. EPA, 2009a). As a result, spatial and temporal heterogeneity is greater for $PM_{10-2.5}$ than for $PM_{2.5}$, because coarser particles have greater settling velocities (Hinds, 1999), and settling velocities are even greater for particles larger than 10 µm. Thus, spatial gradients are steepest near sources, such that measured concentrations of larger particle sizes tend to be most representative of the ambient air in areas in close proximity to the monitor, with higher concentrations likely to occur closer to the source and decreasing concentrations with increasing distance from the source. This issue has been thoroughly discussed in the 2006 Pb AQCD (U.S. EPA, 2006b). It has also been acknowledged in previous Pb AQCDs, with a lengthy discussion appearing in the 1977 AQCD (U.S. EPA, 1986b, 1977).

The low-volume Pb-PM_{10} FRM sample collection method specifies use of a low-volume PM_{10} sampler that meets specified design criteria (40 CFR part 50, Appendix Q). Ambient airborne PM is collected on a polytetrafluoroethylene (PTFE) filter for 24 hours using active sampling at local conditions with a low-volume PM_{10} sampler and analyzed by X-ray fluorescence (XRF). In recognition of the steep spatial gradients associated with sources of ultracoarse particles, ambient Pb sampled using the FRM for Pb-PM_{10} is allowed in certain instances where the expected Pb concentration does not approach the NAAQS and no sources of ultracoarse Pb are nearby.

Alternative Sample Collection Methods

In addition to the FRMs for ambient Pb sample collection, a range of other PM sampling methods are available for collecting samples for Pb analysis. These include FRM sampling methods for PM that have also been used for collection of samples for Pb analysis, sampling methods in use in other sampling networks such as the CSN, IMPROVE and National Air Toxics Trends Stations (NATTS) networks described in Section 3.4.2, and other sampling methods that have been used to measure airborne Pb concentrations in research studies unrelated to network applications; these methods are

listed in Table 3-3. Most of these methods have been described in considerable detail in the 2004 PM AQCD (U.S. EPA, 2004). Table 3-3 also lists key conditions of capture for each method, including particle size, inlet type, collection medium, and flow rate. Not all methods included in Table 3-3 and in subsequent paragraphs have been applied to Pb-PM collection, but these methods represent potential alternative methods for this purpose. It should also be noted that not all of the samplers listed in Table 3-3 have been wind tunnel tested for a variety of aerodynamic particle sizes, wind speeds, and wind directions. In addition, some of these samplers are no longer commercially available.

Table 3-3 Airborne PM sampling methods potentially applicable for Pb sampling.

Sampler	Network	Sampler Type	Mass Median Aerodynamic Diameter	Inlet or Fractionator Type	Collection Medium	Typical Flow Rate	Reference
High Volume TSP	Pb-FRM	Single Channel	TSP	Gabled, rectangular	Glass	1130 L/min	U.S. EPA (2011f)

Size discrimination is usually accomplished with impactors or cyclones. With impactors, PM is forced through a jet at high speed, and particle inertia carries particles above a given size into a collection surface downstream of the jet, while smaller particles follow the air stream around the collector. In multistage impactors, a series of successive stages of jets are used to collect a range of particle sizes. The micro-orifice uniform deposit impactor (MOUDI) is a widely used multistage impactor. The impaction process and performance of various impactors, including the WINS and MOUDI, has been described in detail in the 2004 PM AQCD (U.S. EPA, 2004). The biggest concern in collection by impaction is particle bounce, which occurs when particles collide with the collection surface but bounce off the collection stage into the air stream and are not actually collected. Considerable effort has been devoted to minimizing errors due to bounce in FRM samplers, and this has been thoroughly discussed in the 2004 PM AQCD (U.S. EPA, 2004). An alternative to impaction that also eliminates particle bounce is the use of an air sampling cyclone. In the CSN and IMPROVE networks, cyclones are used to remove particles larger than 2.5 µm. An air sampling cyclone brings air into a tangential jet and directs flow against a circular wall, where particles larger than a given size are removed by centrifugal and gravitational forces.

Collection medium and flow rate are two other key features of a sampling method. One advantage of low volume sampling is its suitability for collection of samples for XRF analysis. Because Pb in $PM_{2.5}$ is analyzed by XRF in the CSN and IMPROVE networks, sampling methods that employ Teflon filters suitable for XRF analysis have been developed for these networks. In practice, this restricts sampling for airborne Pb to low volume samplers with a convenient filter size. This also holds true for the Pb-PM_{10} FRM sampling, which is also restricted to low volume PM_{10} samplers because XRF has been designated as the FRM for Pb-PM_{10} analysis. An additional practical advantage of available low volume samplers over the existing high volume Pb-TSP FRM is that established low volume $PM_{2.5}$ and PM_{10} sampling methods are not dependent on wind direction. However, this has to do with sampler design rather than flow rate, and there are high volume PM_{10} sampling methods, including the PM_{10} FRMs, that are also free of wind direction bias. These would be suitable for Pb measurement with other analytical methods, such as ICPMS, and could have a potential advantage of providing more material in locations with very low concentrations.

Alternatives to TSP sampling have been developed that collect a particle size range that extends beyond 10 μm. Early examples include samplers for "inhalable particulate matter" that were designed to have cut points for 50% sampling efficiency of 15 μm aerodynamic diameter. These included the Andersen Inhalable Particulate Sampler (Model 7000, Thermo Electron, Smyrna, GA) and the Sierra Dichotomous Sampler (Series 244, Sierra Instruments, Monterey, CA), which were evaluated and compared to each other and to TSP sampling in both co-located field comparisons (Solomon et al., 1982) and wind tunnel studies (Watson et al., 1983), with the result that poor agreement was observed for low or high wind speeds, or when much coarse particulate matter was present. For example, the Dichotomous Sampler collected on average only 73 ± 18% as much mass as the Inhalable Particulate Sampler, and differences were attributed to differences in the efficiency of large particle collection (Solomon et al., 1982).

More recently, a variety of inlets have been developed for low volume TSP sampling. The omnidirectional TEOM TSP Inlet (Model 10-002929, Rupprecht & Pataschnik Co., Inc, Albany, NY) was designed to sample 100 μm particles in still air with the suction velocity equal to the terminal velocity of a 100 μm diameter unit density sphere. However, substantial PM mass loss was reported for this inlet and attributed to anisokinetic sampling conditions that led to inefficient sampling of large particles (Jerez et al., 2006). The inefficient sampling of larger particles by the TSP inlet was also observed by Kenny et al. (2005), who carried out wind tunnel tests of 1) a commercially available omnidirectional low volume (16.67 liters/minute) TSP inlet, and 2) a louvered dichotomous inlet designed to select particles from a moving airstream and transmit them to a downstream PM_{10} impactor. They observed that the TSP inlet exhibited low

sampling efficiency even for larger particles within the PM_{10} range, and concluded that it is likely to give biased PM concentrations that vary with external winds when large particles are present. However, for the louvered dichotomous inlet, Kenny et al. (2005) reported high sampling efficiencies with little influence of wind speed across the full PM_{10} particle size range, and a 50% cutpoint at around 15 μm. For the full scale TSP, inlet sampling efficiencies for 46 μm particles were 17% for a 1 meter/second wind speed and 28% at 2 meters/second.

Evaluation of other available TSP samplers also reveals variability among sampler models. The Texas A&M Low Volume TSP Sampler (Coulter Counter Multisizer III, Beckman Coulter, Inc., Fullerton, CA) was designed based on applicable guidelines for high volume TSP samplers for use in sampling particulate matter from agricultural sources (Wang et al., 2005b; Wanjura et al., 2005), and mass collected with this sampler has been compared to an Andersen multistage impactor (Model 20-800, Thermo Electron Co., Smyrna, GA) in an intercomparison exercise (Park et al., 2009a). Measurements by the Anderson Impactor were 97% higher for the PM_4 fraction and 14% higher for the PM_{10} fraction compared with the Texas A&M TSP sampler. Jerez et al. (2006) compared the University of Illinois at Urbana Champaign (UIUC) isokinetic TSP sampler with a tapered element oscillating microbalance (TEOM) TSP sampler (Series 1400a, Rupprecht and Pataschnik Co., Inc., Albany, NY) when measuring dust concentrations in a swine and chicken houses in Illinois, Indiana, Minnesota, and Texas between September to December, 2003. The TEOM measured concentrations that were 26-117% of the UIUC sampler; for 86 of 90 measurements, the TEOM measurements were lower than the UIUC measurements.

Other new approaches to high volume sampling include “saturation samplers” or low volume (5 liters/minute) samplers designed for high spatial coverage of PM_{10} and $PM_{2.5}$,. Chen et al. (2011a) provide an intercomparison among portable MiniVol (Airmetric, Eugene, OR), Omni (BGI, Inc., Waltham, MA), and dichotomous samplers (Model 2025, Rupprecht and Pataschnik, Albany, NY) and two FRMs (RAAS-100, Andersen, Smyrna, GA; Partisol-FRM 2000, Rupprecht and Pataschnik, Albany, NY) for PM_{10} and $PM_{2.5}$ measurements. Chen et al. (2011a) observed R^2 of 0.95-0.98 with average mass concentrations within 4% among the PM_{10} measurements. They observed R^2 of 0.96-0.99 and average mass concentrations within 9% among the monitors for $PM_{2.5}$ measurements. Hitzenberger et al. (2004) found more variability among portable $PM_{2.5}$ and PM_{10} monitors when performing intercomparisons in Melpitz, Germany. $PM_{2.5}$ was measured with stacked filter units (SFU) (developed at Ghent University), a TEOM (Model 1400A, Rupprecht and Pataschnick, Albany, NY), a Digitel (Model DHA-80) high volume sampler, an electrical low pressure impactor (ELPI) (Outdoor-ELPI, Dekati, Ltd.), a TSP, and a MOUDI. PM_{10} was measured with SFUs, a TSP (manufacturer not provided) with

30 L/min and 70 L/min Berner impactors, and a MOUDI (model and manufacturer not provided). Based on Hitzenberger et al.'s (2004) reported average mass concentrations, the $PM_{2.5}$ samplers ranged from 73% (TEOM) to 180% (ELPI) of the average. When trimming the extrema, the average $PM_{2.5}$ concentrations measured within 10% of the overall average. For the PM_{10} monitors, Hitzenberger et al.'s (2004) reported average mass concentrations ranged from 83% (one SFU, MOUDI) to 123% (two SFUs) of the overall average. When trimming the extrema, the average PM_{10} concentrations were within 13%.

Passive samplers have also recently been used for capturing spatial variability of ambient air Pb concentrations. Field testing of the Wagner and Leith Passive Sampler (University of North Carolina) illustrated very good agreement with a cascade impactor (difference within 5% for three sampling events) for $PM_{2.5}$ in certain cases and very poor agreement (difference of -51% and -110%) in others; Wagner and Leith (2001) attributed the poor agreement to low $PM_{2.5}$ mass events. PM_{10} agreement was 14-65% and was attributed to potential phenomena such as agglomeration on the passive sampler and water evaporation from the impactor sample. However, when comparing the Wagner and Leith Passive Sampler for $PM_{10-2.5}$ with $PM_{10-2.5}$ calculated by differencing measurements obtained from co-located or dichotomous FRMs for PM_{10} and $PM_{2.5}$, Leith et al. (2007) observed that Passive Sampler $PM_{10-2.5}$ measurements integrated over at least one week were within one standard deviation of the $PM_{10-2.5}$ obtained from co-located or dichotomous FRMs. Kumar et al. (2012) and Lagudu et al. (2011) illustrated how the Wagner and Leith Passive Sampler can be coupled with computer-controlled scanning electron microscopy (CCSEM) to produce concentrations of Pb-$PM_{10-2.5}$ in samples taken across the cities of Syracuse, NY and Rochester, NY, respectively.

These results illustrate that alternative sampling options to TSP are available to capture ambient air Pb concentrations for particles with a cutpoint of approximately 15 μm or higher, and the state of the science for sampling in this particle size range is progressing, including better documentation of performance and field intercomparison data. In general, both the historical and recently available alternatives to the traditional TSP sampler illustrate that samplers designed to collect particles up to a size range greater than 10 μm have not performed or compared as well as samplers designed to collect smaller particles, and the challenge of achieving good performance for collection of particles size ranges greater than 10 μm has not been limited to the TSP sampler. This is expected given the inherent difficulties associated with large particle sampling (Garland and Nicholson, 1991). In spite of this, good performance by recently developed samplers, including the louvered TSP inlet evaluated by Kenny et al. (2005) show promise for good performance in collection of a particle size range extending beyond 10 μm. The primary route of Pb exposure is hand-to-mouth contact with deposited Pb on soil or dust having

substantially larger size fractions compared with airborne Pb particles, as described in Section 4.1. The relevant particle size distribution for ambient sampling is smaller than the size distribution of the settled dust. Particles larger than about 20 μm are generally considered too large to be transported for more than a few seconds under typical conditions; see Section 3.3.1.3. If preliminary results concerning the TSP louvered inlet and other TSP alternatives are verified, this may be very close to the practical limit for good sampling data quality. It follows that 15 to 20 μm may be a practical limit for both good sampling data quality and representative sampling in a limited area.

3.4.1.2 Sample Analysis: Federal Reference and Federal Equivalence Methods

As described in Section 3.4.1.1, measurements for determinations of NAAQS compliance must be made with FRMs or FEMs. As of October 12, 2011, 1 manual reference method and 25 manual equivalent methods for sample analysis had been approved for Pb (http://www.epa.gov/ttn/amtic/files/ambient/criteria/reference-equivalent-methods-list.pdf). The FRM for Pb (Pb-TSP) was promulgated in 1979 and is based on flame atomic absorption spectroscopy (AAS) (40 CFR Part 50, Appendix G). Ambient air suspended in PM is collected on a glass fiber filter for 24 hours using a high volume air sampler. Pb in PM is then solubilized by extraction with nitric acid (HNO_3), facilitated by heat, or by a mixture of HNO_3 and hydrochloric acid (HCl) facilitated by ultrasonication. The Pb content of the sample is analyzed by atomic absorption spectrometry using an air-acetylene flame, using the 283.3 or 217.0 nm Pb absorption line, and the optimum instrumental conditions recommended by the manufacturer. Several FEMs have been approved based on a variety of principles of operation have been approved, including inductively coupled plasma optical emission spectrometry, and inductively-coupled plasma mass spectrometry (ICPMS).

Atomic Absorption Spectrometry

AAS is the basis for the existing FRM. Atomic absorption spectrometry was first developed in the 19th century, and became widely used in the 1950s. More than 70 elements can be analyzed by AAS. Typically a liquid sample is nebulized into a flame with sufficient heat for elements to be atomized. The liquid specified by the FRM is a nitric acid extract of a glass fiber filter used for collection of suspended PM with a high volume sampler. The atomized sample is then irradiated with visible light at a specific wavelength to promote an electronic transition to a short-lived excited state, resulting in absorption of the light. Elemental selectivity is achieved because light absorption is

specific to a particular electronic transition in a particular element. As a result, absorption of light at a given wavelength generally corresponds to only one element. The flame is irradiated with a known quantity of light and intensity of light is measured on the other side of the flame to determine the extent of light absorption in the flame. Using the Beer-Lambert law the concentration of the element is determined from the decrease in light intensity due to sample absorption.

A more sensitive variation of atomic absorption spectrometry for most elements is graphite furnace atomic absorption spectrometry (GFAAS). Instead of introducing the sample into a flame, the liquid sample is deposited in a graphite tube that is then heated to vaporize and atomize the sample.

Inductively-Coupled Plasma Mass Spectrometry

Inductively coupled plasma mass spectrometry (ICPMS) is a sensitive method of elemental analysis developed in the late 1980s. Argon (Ar) plasma (ionized gas) is produced by transmitting radio frequency electromagnetic radiation into hot argon gas with a coupling coil. Temperatures on the order of 10,000 K are achieved, which is sufficient for ionization of elements. Liquid samples can be introduced into the plasma by extracting samples in an acid solution or water, and nebulizing dissolved elements. Resulting ions are then separated by their mass to charge ratio with a quadrupole and signals are quantified by comparison to calibration standards. While solid samples can be introduced by laser ablation, nebulization of liquid extracts of PM collected on Teflon filters is more typical. One major advantage of ICPMS over AAS is the ability to analyze a suite of elements simultaneously. An additional advantage is low detection limits of 50-100 parts/trillion for Pb.

Inductively-Coupled Atomic Emission Spectroscopy

Inductively coupled atomic emission spectroscopy (ICP-AES) also generates ions from elements with a hot Ar plasma, similar to ICPMS. Excited atoms and ions are produced, and these emit electromagnetic radiation with frequencies characteristic of a particular element. Intensity of emission is used to determine the concentration of an element in the sample. Elements are extracted from filter samples and nebulized into the plasma.

Energy Dispersive X-ray Fluorescence

In energy dispersive X-ray fluorescence spectrometry a beam of X-ray photons from an external excitation source is applied to a sample, causing ejection of inner shell electrons

from elements in the sample. Because inner shell electrons have higher electron binding energies than outer shell electrons, the ejection of the inner shell electron induces an energetically favorable electronic transition of an outer shell electron to replace the ejected electron. The energy released as a result of this transition is in the form of electromagnetic radiation, corresponding to the difference in electronic binding energies before and after the transition. The energy released is typically in the X-ray portion of the electromagnetic spectrum. The release of electromagnetic radiation as a result of an electronic transition is defined as fluorescence. Fluorescence energies associated with electronic transitions depend on atomic structure, and vary between elements. As a result, X-ray fluorescence energy is uniquely characteristic of an element, and X-ray intensity at a given energy provides a quantitative measurement of elemental concentration in the sample. The X-rays are detected by passing them through a semiconductor material, resulting in an electrical current that depends on the energy of the X-ray.

3.4.1.3 Other Analysis Methods for Total Pb

Several other methods that have not been designated as FRM or FEM methods have also been frequently used to obtain atmospheric Pb measurements. These include proton induced x-ray emission (PIXE), X-ray photoelectron spectroscopy (XPS), and other methods

PIXE

Proton-induced X-ray emission (PIXE) spectroscopy has been widely used to measure Pb in atmospheric PM. In PIXE, a high-energy proton beam passes through the sample, causing electrons to be excited from inner shells. The x-rays emitted when electronic transition occur to replace the inner shell electrons are characteristic of an element and can be used to identify it. Development of PIXE for analysis of airborne PM was reviewed by Cahill et al. (1981). Numerous applications of PIXE to analysis of airborne Pb-PM have been reported in the past five years (Cohen et al., 2010; Waheed et al., 2010; Sanchez-Ccoyllo et al., 2009; Chan et al., 2008; Johnson et al., 2008; Cong et al., 2007; Ariola et al., 2006; Johnson et al., 2006; Wåhlin et al., 2006).

XPS

X-ray photoelectron spectroscopy (XPS), also called electron spectroscopy for chemical analysis (ESCA) has been used to determine Pb concentrations on materials surfaces, including atmospheric PM (Finlayson-Pitts and Pitts, 2000). A fixed frequency X-ray

beam causes inner shell electrons to be emitted and kinetic energy of ejected electrons is measured. Binding energy characteristic of an element can be calculated from the measured kinetic energy, allowing identification of the element. XPS can also provide information about an element's chemical environment or oxidation states because of chemical shifts in binding energy caused by differences in chemical environment. There have been some recent applications of XPS to airborne PM, concluding that Pb was mostly in the form of Pb sulfate (Qi et al., 2006). XPS analysis is a surface technique that is suitable only to a depth of 20-50Å.

Other Total Pb Methods

Anodic stripping voltammetry, atomic emission spectroscopy, and colorimetry have also been used for measurement of atmospheric Pb (Finlayson-Pitts and Pitts, 2000). In anodic stripping voltammetry, metal ions are reduced to metallic form and concentrated as an amalgam on a suitable electrode (e.g., a mercury (Hg) amalgam on a mercury (Hg) electrode). This is followed by re-oxidation in solution, which requires "stripping" the reduced metal from the electrode. Emission spectroscopy can be compared to the existing FRM for Pb based on AAS. In atomic absorption spectroscopy radiation absorbed by non-excited atoms in the vapor state is measured. In emission spectroscopy, radiation due to the transition of the electron back to ground state after absorption is measured, and the energy of the transition is used to uniquely identify an element in a sample. Colorimetric methods are wet chemical methods based on addition of reagents to a Pb containing solution to generate measurable light absorbing products. These methods are less sensitive than ICPMS, XRF, and PIXE and their use is declining as more sensitive methods become more widely used, but have advantages regarding simplicity and cost.

3.4.1.4 Sequential Extraction

Sequential extraction has been widely used to further classify Pb for various purposes, including bioavailability, mobility, and chemical speciation. In general the more easily extractable Pb is considered more mobile in soil and is more bioavailable to organisms. This approach has also been used widely in characterization of airborne PM. In its original application (Tessier et al., 1979) metals extraction solvents were selected to correspond to common species present in soil, and metals were classified as exchangeable, bound to carbonates, bound to iron and manganese oxides, bound to OM, and residual. Extraction was carried out with successively stronger solutions, starting with magnesium chloride ($MgCl_2$) for removal of exchangeable metals and ending with hydrofluoric and perchloric acids for removal of residual metals. Pb was one of the

elements originally studied by Tessier et al. (1979) as well as one the elements analyzed when Tessier's scheme was first applied to airborne PM (Fraser and Lum, 1983).

Tessier's scheme was modified and optimized for airborne PM over time (Fernandez Espinosa et al., 2002) and additional extraction schemes were also developed (Chester et al., 1989), including the simplest case of two fractions corresponding to soluble and insoluble fractions (Falta et al., 2008; Canepari et al., 2006; Voutsa and Samara, 2002). The variety of methods in current use was recently thoroughly reviewed by Smichowski et al. (2005). With the recognition that biological processes involving deposited PM metals were related to their solubility (U.S. EPA, 2009a), sequential extraction methods or simpler schemes to divide metals into water and acid soluble fractions were increasingly applied to PM samples to obtain data not just on total metal concentration but also on water soluble concentration (Graney et al., 2004; Kyotani and Iwatsuki, 2002; Wang et al., 2002). Compared to other elements, a large fraction of total Pb is soluble (Graney et al., 2004). Recent advances in this area have included application to size fractionated PM (Dos Santos et al., 2009; Birmili et al., 2006), time resolved measurements (Perrino et al., 2010), and an extensive comparison of different fractionation schemes (Canepari et al., 2010). Sequential extraction with two or more fractions is becoming more widely used for characterization of Pb-PM in a variety of sources (Canepari et al., 2008; Smichowski et al., 2008; Poykio et al., 2007; Sillanpaa et al., 2005) and locations (Perrino et al., 2010; Dos Santos et al., 2009; Cizmecioglu and Muezzinoglu, 2008; Dahl et al., 2008; Sato et al., 2008; Annibaldi et al., 2007; Richter et al., 2007; Al-Masri et al., 2006; Canepari et al., 2006; Fujiwara et al., 2006; Wang et al., 2006c; Yadav and Rajamani, 2006; Gutierrez-Castillo et al., 2005; Heal et al., 2005), leading to a better understanding of mobility characteristics of Pb in airborne PM.

3.4.1.5 Speciation Techniques

X-ray absorption fine structure (XAFS)

There have been few attempts to speciate Pb in atmospheric PM. However, recently X-ray absorption fine structure (XAFS) has been applied to PM and road dust to obtain Pb speciation data from direct analysis of particle surfaces. In XAFS the absolute position of the absorption edge can be used to determine the oxidation state of the absorbing atom, and scattering events that dominate in the near edge region provide data on vacant orbital energies, electronic configurations, and site symmetry of the absorbing atom that can be used to determine the geometry of the atoms surrounding the absorbing atom. XAFS can be divided into two spectral regions. X-ray absorption near edge structure (XANES) is the region of the x-ray absorption spectrum up to 50 eV above the absorption edge

observed when an inner shell electron is electronically excited into unoccupied states, and Extended X-ray Absorption Fine Structure (EXAFS) up to 1 keV above the absorption edge. Both have been applied recently to Pb in PM. XANES spectra of Pb coordination complexes with a wide range of environmentally relevant ligands have been reported (Swarbrick et al., 2009). XANES has been used to show that several different Pb species are probably present in urban airborne PM (Funasaka et al., 2008) and urban road dust (Barrett et al., 2010). XANES has been used to differentiate between Pb chromate, Pb-sorbed minerals, Pb chloride, Pb oxide, Pb carbonate, Pb sulfide and Pb sulfate are probably present in urban PM and road dust samples (Barrett et al., 2010; Funasaka et al., 2008; Tan et al., 2006). XANES has also been used to investigate Pb in air samples thought to be complexed with humic substances from soil (Pingitore et al., 2009) and to investigate the speciation of atmospheric Pb in soil after deposition (Guo et al., 2006b). EXAFS has been applied to emission sources to show Pb from a sinter plant was mainly carbonate (Sammut et al., 2010). XAFS has only been applied to airborne PM very recently and shows promise for chemical speciation of airborne metals, including Pb.

GC-ICPMS and HPLC-ICPMS

Environmental analytical methods for organolead compounds prior to 2000 were generally time consuming and costly, requiring extraction, derivatization, and detection (Quevauviller, 2000). These have been thoroughly reviewed (Pyrzyńska, 1996) and method intercomparison studies have been conducted (Quevauviller, 2000). More recently, speciation of organometallic compounds in environmental samples has usually carried out by coupling a chromatographic separation step with a mass spectrometry-based multi-element detection system capable of analyzing a wide range of elements along with Pb, and these approaches have also been recently reviewed (Hirner, 2006). Chromatographic systems in common use are gas chromatography (GC) and high performance liquid chromatography (HPLC). Detection systems most commonly used are an inductively coupled plasma mass spectrometer (ICP-MS [ICPMS]), electron impact ionization mass spectrometry (EI-MS), and electrospray ionization mass spectrometry (ESI-MS) (Hirner, 2006). Using these techniques, organometallic species are separated from each other based on differences in retention times on chromatographic columns, and elemental Pb is determined by the ICPMS used as a detector downstream of the column to measure elemental Pb in the pure compounds after chromatographic separation. Pb speciation analysis has benefited from the development of HPLC-ICPMS in particular (Quevauviller, 2000). Recent advances in metal speciation analysis in environmental samples by HPLC-ICPMS have been extensively reviewed (Popp et al., 2010). HPLC-ICPMS has been used for analysis of Pb complexes with humic substances (Vogl and Heumann, 1997), which could be relevant for resuspended soil and road dust. GC-ICPMS

has been more widely used for separation and analysis of methyl and ethyl Pb species in atmospheric PM (Poperechna and Heumann, 2005; Jitaru et al., 2004; Leal-Granadillo et al., 2000).

Pb-Isotope Ratio Analysis

Classifying Pb by its relative isotopic abundance has also proved useful for a variety of purposes, including the determination of its geochemical origins in natural samples and the relative contributions of coal burning, mining, smelting, and motor vehicle emissions in polluted samples (Farmer et al., 1996). Typically, isotopes of Pb (^{208}Pb, ^{207}Pb, ^{206}Pb, and ^{204}Pb) are measured in a sample using mass spectrometry, and then ratios of the isotopes are calculated to obtain a "signature." Isotopes of ^{208}Pb, ^{207}Pb, and ^{206}Pb are substantially more abundant than ^{204}Pb, but they vary depending on the geologic conditions under which the ore was produced through decay of different isotopes of uranium and thorium (Cheng and Hu, 2010). Isotope ratio analysis was first applied to airborne PM in 1965 to identify the impact of motor vehicle exhaust on marine and terrestrial Pb deposition in the Los Angeles area (Chow and Johnstone, 1965). More recently, high resolution ICPMS has also proved to be a sensitive tool for isotope ratio analysis. High resolution ICPMS was first applied to geological samples (Walder and Freedman, 1992), and has since been widely used for determination of Pb isotope ratios in airborne PM samples. Pb isotope ratios have been measured in a number of recent studies in a variety of locations to investigate the origin of airborne Pb (Knowlton and Moran, 2010; Noble et al., 2008; Hsu et al., 2006; Widory, 2006). Shotyk and Krachler (2010) also used Pb isotopes to demonstrate that the fate of Pb from runoff can be different from Pb with different origins. They observed that humus PM impacted by leaded on-road gasoline that are derived from soil surfaces are likely to be more easily transferred to sediments than Pb of other origins, with substantial amounts retained by lakes.

Recent studies have examined the use of Pb isotope ratios as a tool for source apportionment. Duzgoren-Aydin and Weiss (2008) provide caveats for using isotope ratio analyses. They point out that Pb isotope ratios may vary when Pb from several sources of different geological origins are introduced to the same location. Duzgoren-Aydin (2007) warned that the presence of a complex mixture of contaminants containing common Pb isotopes can lead to an overestimation of the contribution of one source (e.g., soil contaminated by Pb emissions from on-road gasoline) and an underestimate of another source, such as that from industry. For this reason, Cheng and Hu (2010) suggest that Pb isotope analysis only be used when the investigators are confident that the isotopic signatures of various sources differ substantially. Pb recycling and international trading may cause more blending of Pb from various sources, so that there is less heterogeneity

in the Pb isotopic signatures sampled. Additionally, Cheng and Hu (2010) point out that the isotopic signature of Pb in air or soil may change over time with changing source contributions, but historical Pb isotope data are lacking. Duzgoren-Aydin and Weiss (2008) suggest the use of geographical information systems (GIS) mapping of Pb isotopic information to help distinguish potential sources based on location of sources in addition to the sources' isotopic signature.

Gulson et al. (2007) examined the relationships between Pb isotope ratios and source apportionment metrics at urban and rural sites in New South Wales, Australia. In this study, Gulson et al. (2007) performed source apportionment with both principal component analysis (PCA) and a neural network technique called the self-organizing map (SOM) and compared results from each method with $^{206}Pb/^{204}Pb$, $^{207}Pb/^{206}Pb$, and $^{208}Pb/^{206}Pb$ obtained from PM samples, although only $^{206}Pb/^{204}Pb$ results were presented in detail. Wintertime "fingerprints" from both the PCA and SOM methods produced similarly linear relationships with $^{206}Pb/^{204}Pb$, with linearly decreasing relationships between the isotope ratios and the "secondary industry," "smoke," "soil," and "seaspray" source categories. However, the relationships of the isotope ratios with the SOM fingerprints and PCA factors, respectively, were very similar. This finding may have been due to the presence of elements such as black carbon and sulfur in several SOM fingerprints and PCA factors. The authors suggest that this might be related to the presence of several sources, which in combination result in a weak atmospheric signal. Additionally, both $PM_{2.5}$ and TSP samples were utilized for this study, and it was found that similar results were obtained for either size cut. At the urban site, they observed that the $^{206}Pb/^{204}Pb$ ratio decreased over time with increasing contributions of industrial, soil, smoke, and sea spray sources. For the most part, these sources were not substantial contributions to Pb-$PM_{2.5}$ for the rural site. As for the Tan et al. (2006) speciation study described above, no notable differences were observed between the size fractions with regard to isotopic signature.

3.4.1.6 Continuous Pb Monitoring

Development of high time resolution measurement capabilities has advantages for determining peak exposure concentrations and diurnal exposure trends. High time resolution samplers suitable for analysis after sampling by XRF and ICPMS have been developed and applied. The eight-stage Davis Rotating Unit for Monitoring (DRUM) impactor (Raabe et al., 1988; Cahill et al., 1987) collects PM samples with a cascade impactor on Mylar film substrate on a slowly rotating drum, with samples analyzed by XRF. It has been used to measure size and time resolved Pb and other elements with a time resolution of less than 6 hours using x-ray fluorescence (Cahill, 2003; Bench et al.,

2002). The University of Maryland Semi-continuous Elements in Aerosol Sampler (Kidwell and Ondov, 2004, 2001) uses direct steam injection to promote condensational growth of sampled PM at a high flow rate, and accumulates resulting droplets in a slurry by impaction. It has been successfully applied to measurement of Pb and other elements by AAS (Pancras et al., 2006; Pancras et al., 2005) with a 30-minute time resolution. This approach is also suitable for ICPMS analysis. A gas converter apparatus has also been developed to improve transfer of ions to the ICPMS, including Pb, and successfully tested with outdoor air (Nishiguchi et al., 2008). Other high time resolution methods suitable for Pb analysis in PM are under development, including near real-time XRF analysis.

Much of the recent progress in ambient aerosol instrumentation has been related to the development and improvement of single particle mass spectrometry (Prather et al., 1994). Preferential loss as a function of particle size is a concern with this method, but considerable effort has been devoted to optimizing transfer from atmospheric pressure down to time of flight operating pressures with minimal particle loss (Prather et al., 1994). This technique can also be considered as an effective method for real time Pb measurement in PM, including size-resolved measurements from 0.1 to 4.0 µm (Silva and Prather, 1997). Progress has continued in the development of single particle mass spectrometry to quantify elements and organic ion fragments and a number of recent applications that included (Snyder et al., 2009; Johnson et al., 2008; Bein et al., 2007; Reinard et al., 2007; Pekney et al., 2006) or specifically targeted (Salcedo et al., 2010; Moffet et al., 2008a; Murphy et al., 2007) Pb measurements.

3.4.2 Network Design

Four national monitoring networks collect data on Pb concentrations in ambient air and report it to the Air Quality System (AQS).[1] State and local agencies carry out the monitoring at state and local monitoring stations (SLAMS) using FRMs and FEMs and report data to these national networks, which have been established for various purposes. Although these data may be used for other scientific purposes, the SLAMS network is designed primarily with the goal of evaluating compliance with the Pb NAAQS. In addition to FRM monitoring, Pb is also measured within the Chemical Speciation Network (CSN), IMPROVE, and the NATTS networks as described in Section 3.4.2.2. Measurements among these networks are not directly comparable in all cases because of method differences, including the PM size range sampled (TSP, PM_{10}, or $PM_{2.5}$).

[1] The Air Quality System (AQS) is EPA's repository of ambient air quality data. AQS stores data from over 10,000 monitors, 5,000 of which are currently active (http://www.epa.gov/ttn/airs/airsaqs/).

3.4.2.1 NAAQS Monitoring Network

Monitors in the SLAMS network include predominantly those sited in compliance with regulatory requirements for the purposes of judging attainment with the NAAQS. For this purpose, these sites employ FRM samplers coupled with FRM/FEM analysis methods. At the time of the last review, there were approximately 250 sites operating in this network, although analyses at the time indicated incomplete coverage of the larger stationary sources of Pb (U.S. EPA, 2007h). As a result of the review, the Pb NAAQS monitoring requirements were revised. These revisions, some aspects of which were finalized in 2008 and the remainder in December 2010, call for expanded monitoring at both source-oriented and non-source-oriented sites (75 FR 81126, 40 CFR part 58, Appendix D, Section 4.5 to Part 58).[1] Source-oriented monitoring sites are required near sources of Pb air emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. At a minimum there must be one source-oriented site located to measure the maximum Pb concentration in ambient air resulting from each non-airport Pb source estimated to emit Pb at a rate of 0.50 or more tons/year and in locations near those airports at which activities associated with the use of leaded aviation fuel are estimated to result in Pb emissions at a rate of 1.0 or more tons per year.[2] The emission monitoring threshold was established to ensure monitoring near Pb air sources with the greatest potential to cause ambient air concentrations to exceed the Pb NAAQS. The Pb NAAQS measurements required at these sites may be as Pb-TSP or Pb-PM_{10} (75 FR 81126).

Monitoring agencies are also required to conduct non-source-oriented Pb monitoring at each National Core multipollutant monitoring network (NCore)[3] site in a Core Based Statistical Area (CBSA) with a population of 500,000 or more. While non-source-oriented monitoring data can be used for purposes of NAAQS attainment designations, the main objective for non-source-oriented monitoring is to gather information on

[1] EPA Regional Administrators may require additional monitoring beyond the minimum requirements where the likelihood of Pb air quality violations is significant. Such locations may include those near additional industrial Pb sources, recently closed industrial sources, airports where piston-engine aircraft emit Pb and other sources of re-entrained Pb dust (40 CFR, part 58, Appendix D, Section 4.5(c).

[2]The requirement for monitoring near sources emitting 0.5 tons/year or more may be waived if it can be shown that the source will not contribute to a maximum 3-month average Pb concentration in ambient air in excess of 50 percent of the NAAQS level based on historical monitoring data, modeling, or other means (40 CFR, part 58, Appendix D, Section 4.5(a)(ii)).

[3] NCore is a new network of multipollutant monitoring stations intended to meet multiple monitoring objectives. The NCore stations are a subset of the SLAMS network are intended to support long-term trends analysis, model evaluation, health and ecosystem studies, as well as NAAQS compliance. The complete NCore network consists of approximately 60 urban and 20 rural stations, including some existing SLAMS sites that have been modified for additional measurements. Each state will contain at least one NCore station, and 46 of the states plus Washington, D.C., will have at least one urban station.

neighborhood-scale Pb concentrations that are typical in urban areas so to better understand ambient air-related Pb exposures for populations in these areas.

Spatial scales defined for Pb monitoring range from microscale to neighborhood scale, with the most important spatial scales for source-oriented sites to effectively characterize emissions from point sources being microscale and middle scale, and the most important scale for non-source-oriented sites to characterize typical Pb concentrations in urban areas being neighborhood scale [40 CFR Part 58, Appendix D, 4.5(d)]:

- Microscale: This scale is intended to typify areas in close proximity to Pb point sources where it may represent an area impacted by the emissions plume with dimensions ranging from several meters up to about 100 meters.
- Middle Scale: This scale is described as generally representing Pb air quality levels in areas up to several city blocks in size with dimensions on the order of approximately 100 meters to 0.5 km.
- Neighborhood Scale: This scale is to characterize concentrations throughout some relatively uniform land use areas with dimensions in the 0.5 to 4.0 km range. Where a neighborhood site is located away from immediate Pb sources, the site may be very useful in representing typical air quality values for a larger residential area, and therefore suitable for population exposure and trends analyses.

Source oriented monitors near sources estimated to emit 1.0 tons/year Pb were required to be operational by January 1, 2010, and the remainder of the newly required monitors, including the non-source-oriented NCore sites, were required to be operational by December 27, 2011 (75 FR 81126). When the December 2010 Pb network requirements are fully implemented, the Pb NAAQS monitoring network is expected to consist of approximately 270 required monitors including approximately 210 source-oriented monitors and 60 non-source-oriented monitors. Figure 3-14 shows the estimated geographic distribution of Pb NAAQS monitors in the current Pb NAAQS monitoring network. This includes monitors that previously existed and are still in operation, along with those that are newly required.

With the December, 2010 regulations, EPA also required one year of Pb-TSP (FRM) monitoring near 15 airports in order to gather additional information on the likelihood of NAAQS exceedances near airports due to the combustion of leaded aviation gasoline (75 FR 81126). These airports were selected based on three criteria: annual Pb inventory between 0.50 tons/year and 1.0 tons/year, ambient air within 150 meters of the location of maximum emissions (e.g., the end of the runway or run-up location), and airport

configuration and meteorological scenario that leads to a greater frequency of operations from one runway. These characteristics were selected because they are expected, collectively, to identify airports with the highest potential to have ambient Pb concentrations approaching or exceeding the Pb NAAQS. Data from this monitoring study will be used to assess the need for additional Pb monitoring at airports. These 15 sites (Figure 3-15 and Table 3-4) were required to be operational no later than December 27, 2011. Evaluating the air quality impact of piston aircraft operations includes consideration of the seasonal variation in activity by these aircraft. At some of the most active general aviation airports in the country, spring and summer operations (by piston aircraft) can increase as much as 73% over operations in the fall and winter, while at other airports, piston aircraft activity is more consistent throughout the year.

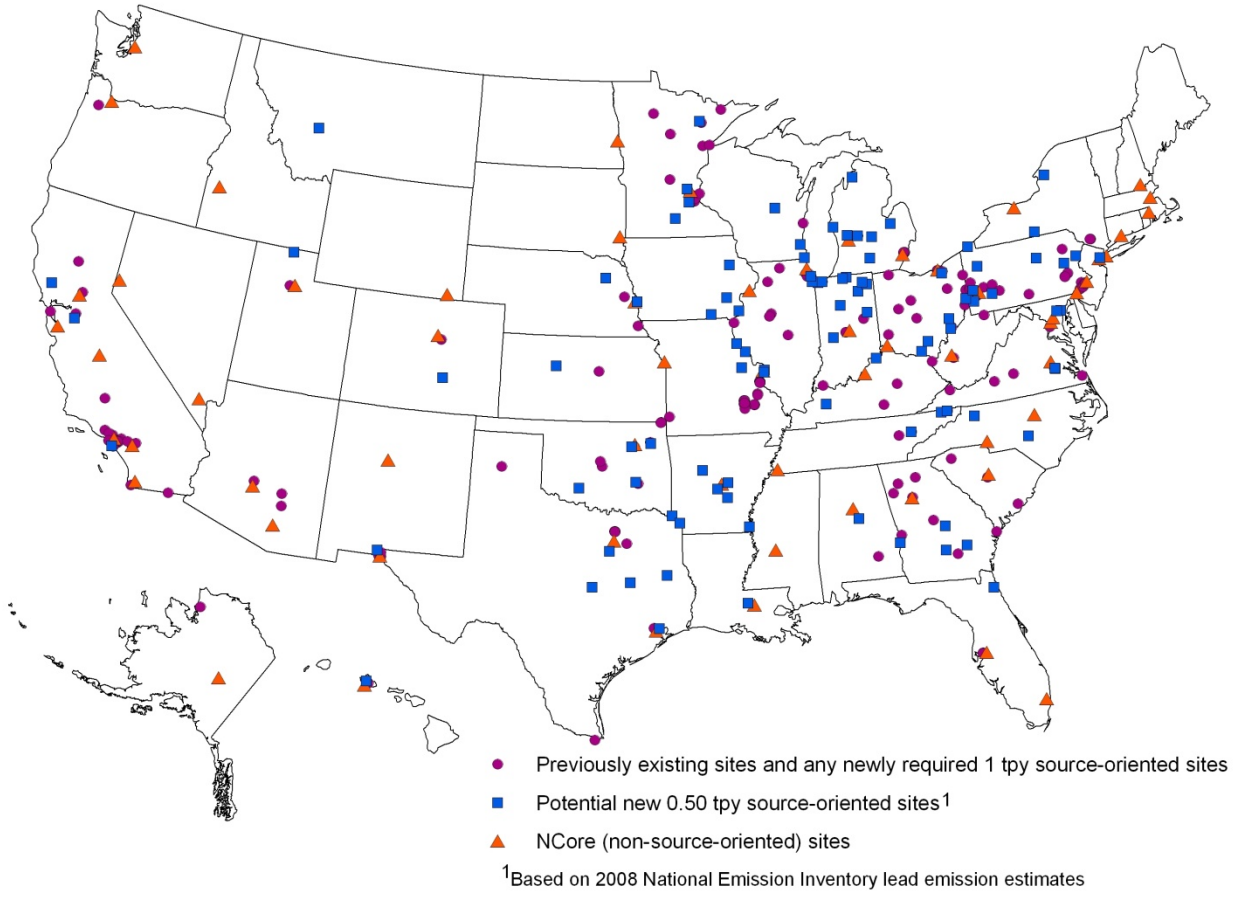

Figure 3-14 Map of monitoring sites in current Pb NAAQS monitoring network.

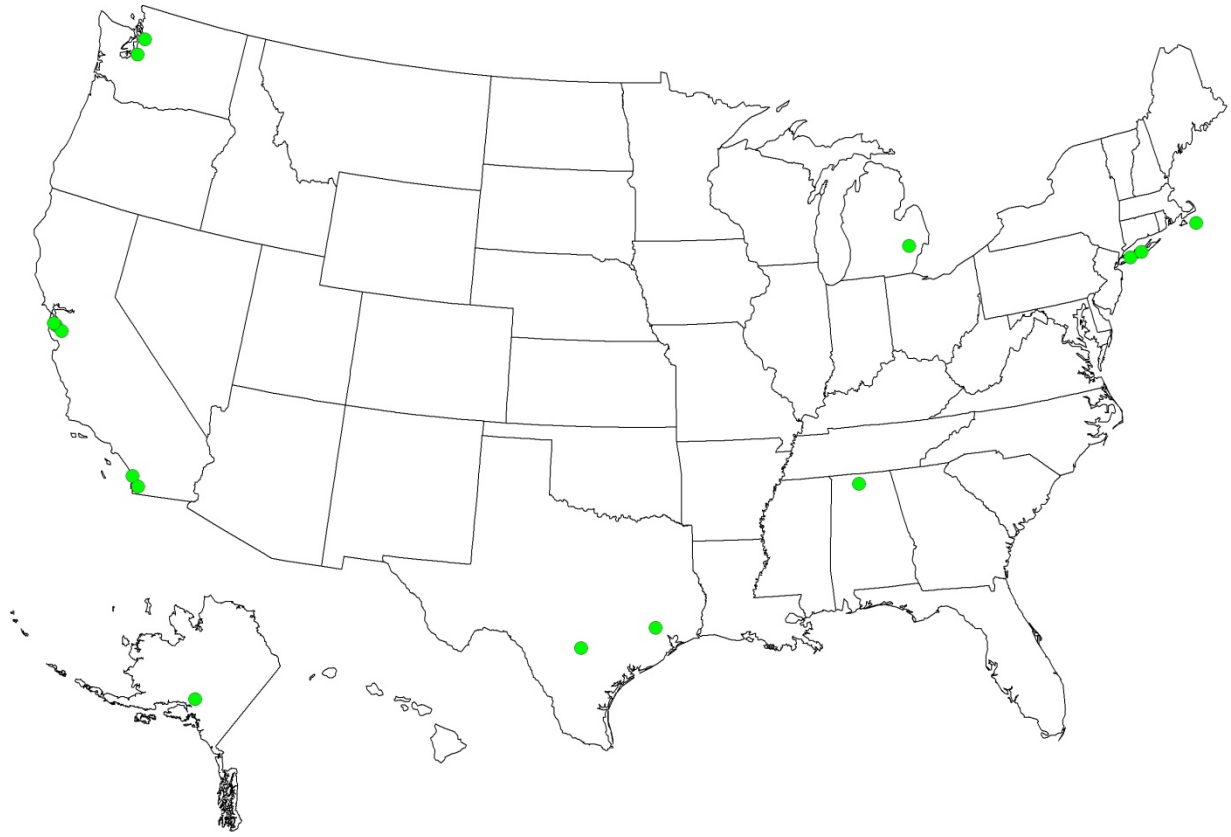

Quality assured results of this study were not available in time for this assessment. Note that the two Santa Clara Co., CA airports are not distinguishable on the map.

Figure 3-15 Fifteen U.S. locations where a study is currently being performed on airport Pb emissions.

Table 3-4 List of 15 airports included in the airport study

Airport	County, State
Merrill Field	Anchorage, AK
Pryor Field Regional	Limestone, AL
Palo Alto Airport of Santa Clara County	Santa Clara, CA
Reid-Hillview	Santa Clara, CA
McClellan-Palomar	San Diego, CA
Gillespie Field	San Diego, CA
San Carlos	San Mateo, CA
Nantucket Memorial	Nantucket, MA
Oakland County International	Oakland, MI
Republic	Suffolk, NY
Brookhaven	Suffolk, NY
Stinson Municipal	Bexar, TX
Northwest Regional	Denton, TX
Harvey Field	Snohomish, WA
Auburn Municipal	King, WA

3.4.2.2 Other Pb Monitoring Networks

In addition to FRM monitoring, Pb is also measured within the Chemical Speciation Network (CSN), Interagency Monitoring of Protected Visual Environments (IMPROVE), and the National Air Toxics Trends Station (NATTS) networks. Pb in $PM_{2.5}$ is monitored as part of the CSN and IMPROVE networks, and Pb in PM_{10} as a part of the National Air Toxics Trends (NATTS) networks (Figure 3-16 and Figure 3-17). These networks are designed to meet different objectives than those of the Pb NAAQS monitoring network.

The purpose of the CSN is to monitor $PM_{2.5}$ species to assist in understanding $PM_{2.5}$ chemistry and for spatial and temporal analyses including annual, seasonal, and sub-seasonal trends (http://www.epa.gov/ttn/amtic/specgen.html). The CSN consists of about 50 long-term trends sites (commonly referred to as the Speciation Trends Network or STN sites) and about 150 supplemental sites, all operated by state and local monitoring agencies. Higher spatial and temporal resolution of the CSN facilitates increased utility in the scientific community, and the data from the CSN also assists states in formulating their emission control strategies, even if the network is not compliance-oriented. Pb is one of 33 elements in $PM_{2.5}$ collected on Teflon filters every third day and analyzed by energy dispersive XRF spectrometry.

In the IMPROVE networks, $PM_{2.5}$ monitors, operated by the National Park Service, largely with funding by EPA, are placed in "Class I" areas (including National Parks and wilderness areas) and are mostly in rural locations. IMPROVE monitoring is intended to establish current visibility conditions, track changes in visibility and determine causal mechanisms of visibility impairment in 156 national parks and wilderness areas. There are 110 formally designated IMPROVE sites and approximately 80 additional sites at various urban and rural areas, informally treated as part of this network and operating under IMPROVE protocols. At these sites, Pb in $PM_{2.5}$ is determined by XRF (UC, 1995).

The NATTS network is designed to monitor concentrations of hazardous air pollutants (HAPs). The NATTS is intended to provide model input, to observe long-term trends in HAP concentrations, and to examine emission control strategies. The NATTS network measures several inorganic HAPs in PM_{10}, along with several volatile organic compounds (VOCs), carbonyls, and polycyclic aromatic hydrocarbons (PAHs). It is operated by state and local agencies and has less extensive national coverage than the other Pb monitoring networks. PM_{10} is collected either by high volume sampling with a quartz fiber filter or low volume sampling with a PTFE filter following EPA Compendium Method IO-3.5 (U.S. EPA, 1999). Pb is one of seven core inorganic HAPs collected on Teflon filters and analyzed by ICPMS. As of December 2009, the network consisted of 27 monitoring stations, including 20 urban and 7 rural stations operating on a one in six day sampling frequency.

Pb monitoring is also conducted at NCore monitoring sites. Monitoring for Pb-$PM_{2.5}$ is currently being conducted at NCore sites as part of the larger CSN (described above). As described in Section 3.4.2, monitoring for Pb-PM_{10} was required to be operational at NCore sites by December 27, 2011. Methods for Pb in $PM_{10-2.5}$ are being developed as part of the $PM_{10-2.5}$ speciation pilot project and may be implemented at some NCore sites in the future.

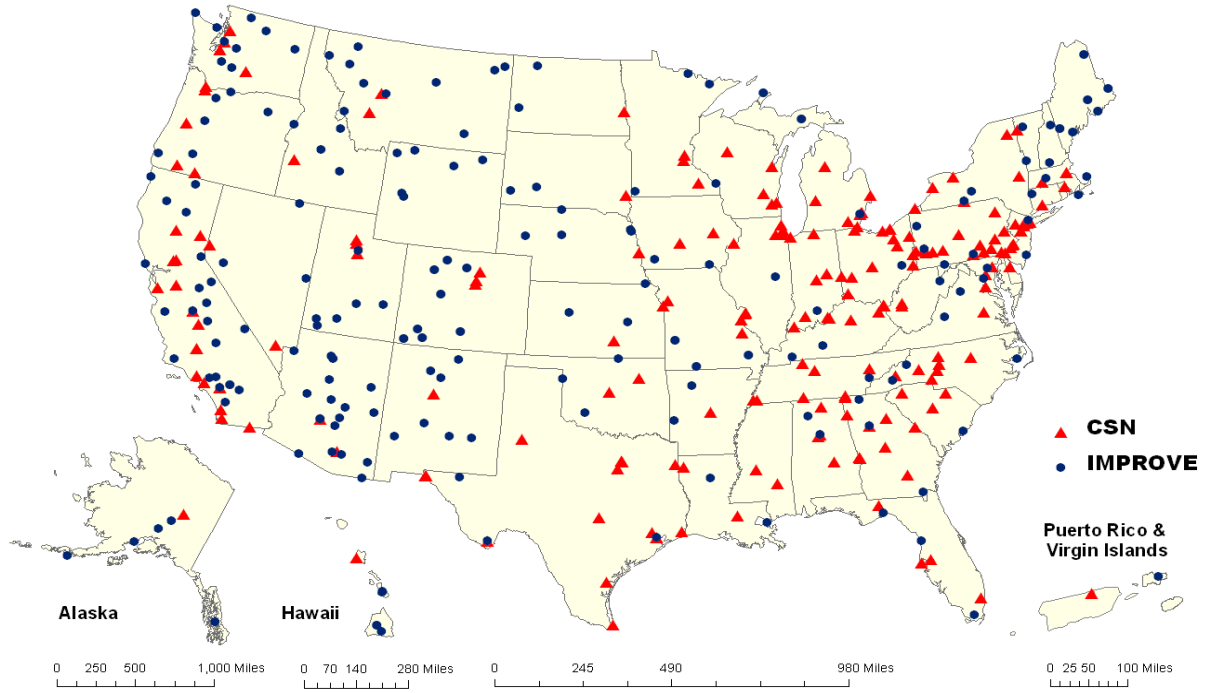

Figure 3-16 Pb-$PM_{2.5}$ monitoring sites for CSN and IMPROVE networks.

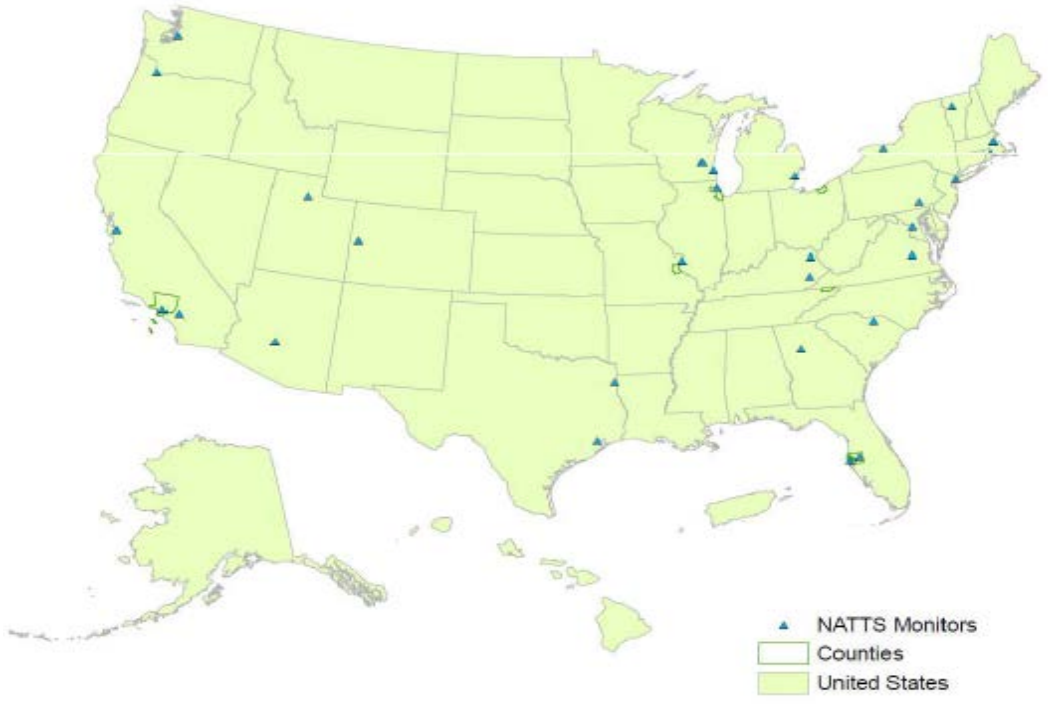

Figure 3-17 Pb-PM_{10} monitoring sites for NATTS network.

3.5 Ambient Air Pb Concentrations

The following section synthesizes ambient air Pb concentration data obtained during the years 2008-2010 with data from studies in the literature presenting Pb concentrations under varied source influences. The 3-month average ambient air Pb concentrations presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 Appendix R and, as such, cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS. For the purpose of analyses within this ISA, monitors were initially designated to be source-oriented if either (1) they were designated in AQS as source-oriented, (2) they were located within one mile of a 0.5 ton/year or greater source as noted in the 2005 NEI (U.S. EPA, 2008a), or (3) they were located within one mile of a 0.5 tons/year or greater source as noted in the 2008 NEI (U.S. EPA, 2011a). The remainder of Pb-TSP FRM monitors reporting to the AQS were classified as non-source-oriented.[1] For this analysis, 120 Pb-TSP FRM monitors were considered source-oriented, while 184 were considered to be non-source-oriented. However, the number of source-oriented and non-source-oriented monitors differed for each analysis year because there were changes in monitor siting. Summary information is presented within this section, and detailed data are included the Chapter 3 Appendix (Section 3.8, Supplemental Material) to this chapter.

3.5.1 Spatial Distribution of Air Pb

3.5.1.1 Variability across the U.S.

This section presents nationwide Pb concentration data measured using source-oriented and non-source-oriented Pb-TSP FRM monitors from 2008-2010 and PM_{10} and $PM_{2.5}$ monitors for 2007-2009. The source and non-source-oriented Pb-TSP FRM monitors present data pertaining to compliance with the current level of the NAAQS. Pb-PM_{10} data obtained from the NATTS network and Pb-$PM_{2.5}$ data from the CSN are presented in the Chaper 3 Appendix (Section 3.8) to illustrate the nationwide distribution of Pb concentration in different classes of particle size. This information is useful to develop a sense of variability in Pb concentrations at a national scale.

[1] Following this initial classification, staff from the EPA Regional offices tasked with acting as liaisons to the states reviewed all monitors listed to fall within their Regions and reported any discrepancies between the initial classification and ground observations of the sites made by EPA Regional or state staff. The source and non-source monitor listing was edited accordingly. The definition of source-oriented monitoring is applied flexibly with input from regions in this ISA because 2008 data were obtained before the latest monitor designation requirements were implemented.

Concentrations of Pb Measured using Pb-TSP Monitors (Source-Oriented and Non-Source-Oriented Monitors)

Maximum 3-month average Pb concentrations[1] were calculated for source-oriented Pb-TSP monitors for 50 counties across the U.S. (1.6% of U.S. counties) during the period 2008-2010. Figure 3-18 illustrates that the level of the NAAQS was exceeded in twenty counties where source-oriented monitoring was performed. The mean exceeded the level of the NAAQS and was skewed toward the 75th percentile of the distribution, indicating that highest ambient air Pb concentrations are near a small subset of the monitors. Upper 90th percentile ambient air Pb concentrations for 2008-2010 occurred in Pike Co., AL, Los Angeles Co., CA, Iron Co., MO, Jefferson Co., MO, and Collin Co., TX. Summary statistics for the monitor-specific one-month and three-month averages are presented in Table 3-5, and detailed statistics for the one-month and three-month averages are provided in Table 3-12, Table 3-14, Table 3-16, and Table 3-18 in the Chapter 3 Appendix (Section 3.8).

[1] Maximum 3-month average Pb concentrations are calculated as the maximum 3-month average of 3 consecutive monthly averages within the 2008-2010 time period.

Table 3-5 Summary data for source-oriented Pb monitors across the U.S., 2008-2010.

	Mean, µg/m^3	Median, µg/m^3	95th%, µg/m^3	99th%, µg/m^3	Max, µg/m^3
Monthly	0.20	0.063	0.86	1.6	4.4
3-mo rolling avg	0.21	0.079	0.88	1.6	2.9

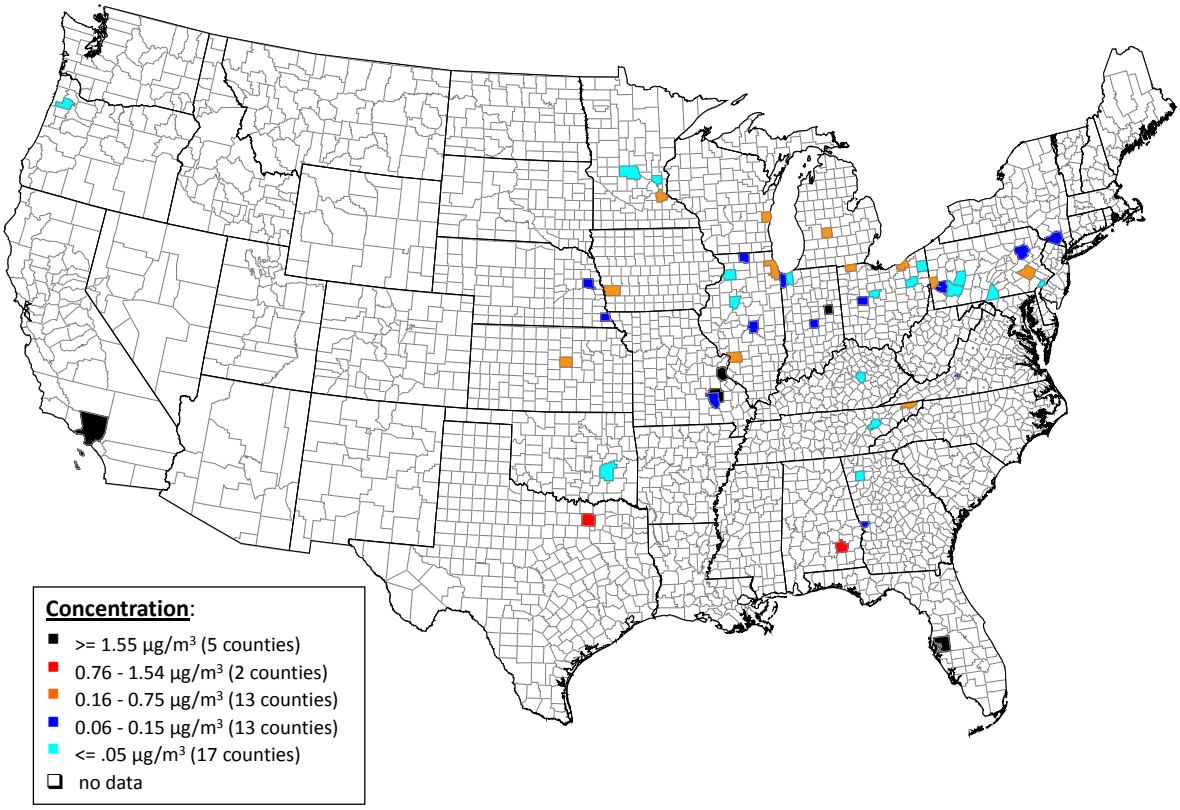

Figure 3-18 Highest county-level source-oriented Pb-TSP concentrations (µg/m^3), maximum 3-month average, 2008-2010.

Maximum 3-month average Pb concentrations were calculated for non-source-oriented Pb-TSP monitors for 47 counties across the U.S. (1.5% of U.S. counties) during the period 2008-2010. Figure 3-19 illustrates that the level of the NAAQS was never exceeded at non-source-oriented monitors. Summary statistics are presented below in Table 3-6, and detailed statistics for the one-month and three-month average and maxima

non-source-oriented Pb-TSP concentrations are provided in Table 3-13, Table 3-15, Table 3-17, and Table 3-19 in the Chapter 3 Appendix (Section 3.8).

Table 3-6 Summary data for non-source-oriented Pb monitors across the U.S., 2008-2010.

	Mean, µg/m^3	Median, µg/m^3	95th%, µg/m^3	99th%, µg/m^3	Max, µg/m^3
Monthly	0.012	0.010	0.040	0.052	0.14
3-mo rolling avg	0.012	0.010	0.037	0.048	0.073

3.5.1.2 Intra-urban Variability

Intra-urban variability is defined as the variation in Pb concentration across an urban area. Because the source characteristics and size distribution of particle-bound Pb can vary considerably in urban areas, spatial variability of Pb concentrations in urban areas may also be high. Moreover, larger Pb-PM tends to settle quickly over short distances after becoming airborne; short settling distances also contribute to high spatio-temporal variability in ambient air Pb concentrations. Such variability may not be detected if one or a small number of central site monitors is in use, so cities with multiple monitors are used to characterize intra-urban variability.

Data for intraurban variability in six U.S. counties are presented in Section 3.8.2 of the Chapter 3 Appendix. When collectively reviewing the data from the six counties, it became apparent that spatial and temporal variability of Pb-PM concentrations were commonly high compared for example with $PM_{2.5}$, which tends to have fairly homogenous concentrations over urban areas because it is subject to secondary formation. Variability was high for areas that included a Pb source, with high concentrations downwind of the sources and low concentrations at areas far from sources. When no large sources of Pb were present, variability of Pb concentrations were lower, and more data were observed to lie below the MDL. For example, Los Angeles County, CA data illustrated very high concentrations adjacent to a Pb recycling facility, but non-source-oriented concentrations were well below the level of the NAAQS at all times, including at sites near roads. As described in Section 3.3, PM size distribution influences how far the particle will travel upon initial emission or resuspension before being deposited. Meteorology, nature of the sources, distance from sources, and positioning of sources with respect to the monitors all appeared to influence the level of concentration variability across time and space.

Airborne Pb near Roads

Five monitors, described in Table 3-7, were selected from the TSP network to examine Pb concentrations in the near road environment. These monitors were selected because they are located in the vicinity of major roadways in urban areas with different characteristics and because they each have long-term data available. Further, based on reviews of emissions inventory information as well as satellite image searches, these sites are not known to be near metals-related industrial sites. Time series of Pb-TSP monthly concentration for all five monitors are shown in Figure 3-20. The annual average over the two sites that were reporting data in 1980 was 0.90 $\mu g/m^3$. This Pb-TSP concentration from 1980 likely reflected the influence of Pb emissions from leaded automobile gasoline (see Figure 3-7 for annual national consumption of leaded motor vehicle gasoline). By

1986, when all five monitors were reporting data, the annual average of Pb-TSP concentration over all five monitors dropped to 0.18 μg/m^3. Over 2001-2010, the annual average Pb-TSP concentration over all sites was 0.02 μg/m^3 with a standard deviation of 0.01 μg/m^3. The highest 2008-2010 design value was 0.04 μg/m^3, which occurred at the Chicago site (17-031-6003) located less than 10 meters to Interstate I-290 at a monitor height of 2 meters AGL. The multi-site average was not substantially larger than the maximum three-month rolling average of 0.012 μg/m^3 for non-source-oriented monitors for the period 2008-2010, and the Pb-TSP concentration varied little over the period 2001-2010. Note that the monitor heights were 2-6 meters AGL, which may be higher than the vertical distance likely traveled by some particles (depending on particle size) following initial resuspension (see Section 3.3.1.3).

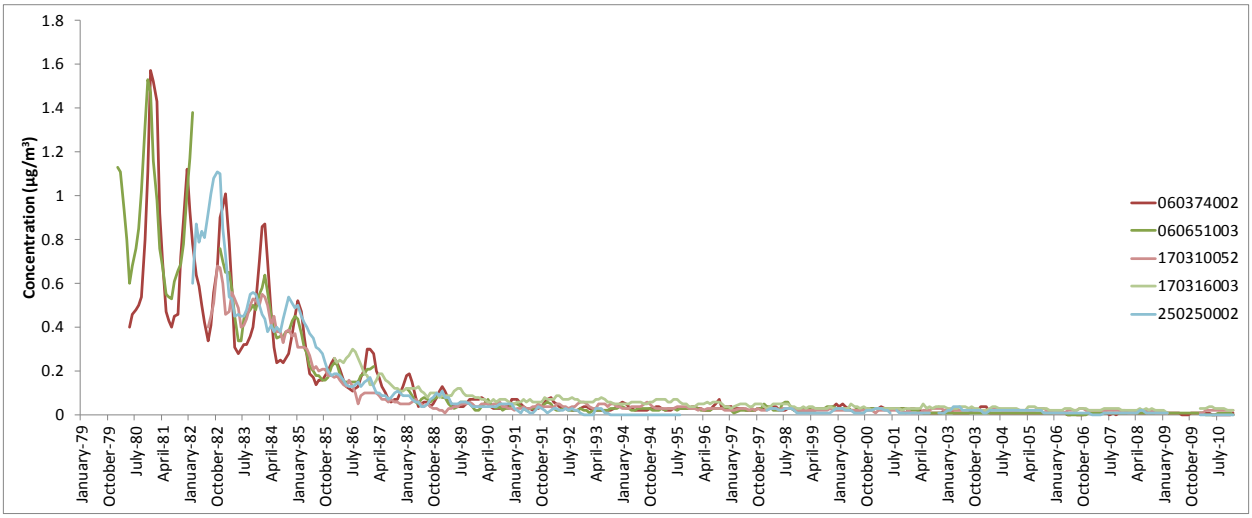
Table 3-7 Sample of U.S. near road Pb TSP monitors

County, State	Site ID	Latitude	Longitude	2008-2010 Design Value ($\mu g/m^3$)[a,b]	Monitor Height (m AGL)	Distance from Roads	Surrounding Area
Los Angeles, CA	06-037-4002	33.82376	-118.18921	0.01	6	500 m to Interstate I-405 (San Diego Freeway), 10 m to Long Beach Blvd	High intensity residential, urban
Riverside, CA	06-065-1003	33.94603	-117.40063	0.01	4	Within 20 m of intersection of Magnolia and Arlington Ave.	High intensity residential, mixed use urban
Cook, IL	17-031-0052	41.96548	-87.749928	0.02[c]	5	Near to intersection of Interstates I-90 and I-94, 80 m to Interstate I-90, 200 m to Interstate I-94, 70 m to railroad	Located at public utilities water pumping station, high density residential urban
Cook, IL	17-031-6003	41.872202	-87.826165	0.04[c]	2	Less than 10 m to Interstate I-290 (Dwight D. Eisenhower Expressway)	Parking lot of Circuit Court of Cook County, ¾ surrounded by Concordia Cemetary
Suffolk, MA	25-025-0002	42.348873	-71.097163	0.02[c]	5	95 m to Intgerstate I-90, inside median of Commonwealth Ave.	High intensity urban, mixed use residential and commercial

[a]The level of the 2008 NAAQS for Pb is 0.15 $\mu g/m^3$ not to be exceeded in any 3-month period. The design value for the 2008 Pb NAAQS is the maximum rolling 3-month Pb-TSP average within the 3-year design period.

[b]The design values shown here are computed for the latest design value period using Federal Reference Method (FRM) or equivalent data reported by States, Tribes, and local agencies to EPA's AQS as of 7/12/2011. Concentrations flagged by States, Tribes, and local agencies as exceptional events (e.g., high winds, wildfires, volcanic eruptions, construction) and concurred by the associated EPA Regional Office are not included in the calculation of these design values. Although the indicator for the 2008 Pb NAAQS is Pb-TSP at "local conditions" (i.e., actual temperature and pressure; parameter 14129), 2008 Pb-TSP data reported in "standard temperature and pressure" (i.e., 25 ° C, 760 mmHg; parameter 12128) are also considered valid for NAAQS comparisons and related attainment/nonattainment determinations if the sampling and analysis methods that were utilized to collect that data were consistent with previous or newly designated FRMs or FEMs and quality assurance requirements were met.

[c]Fewer than 36 rolling 3-month Pb-TSP average data are available at this site for this 3-year period; the value shown here is the highest valid 3-month mean.



Note: Monitor IDs from Table 3-7: Los Angeles, CA: 06-037-4002 (dark red); Riverside, CA: 06-065-1003 (dark green); Two from Cook, IL: [17-031-0052 (light red), and 17-031-6003 (light green)]; and Suffolk, MA: 25-025-0002 (blue).

Figure 3-20 Time series of monthly average Pb-TSP concentration at five near-road monitors.

Airborne Pb near Airports

There have been only a few studies of air Pb concentrations near airports, but they have generally demonstrated consistent results. Levin et al. (2008) summarized findings from measurements at Buttonville Airport near Toronto, Canada that median air Pb-PM_{10} levels were not substantially higher than average reported background levels (0.01 µg/m^3 versus 0.007 µg/m^3) (Conor Pacific Environmental Technologies Inc, 2000), although the Buttonville analysis averaged upwind and downwind data. The maximum 24-hour concentration measured in this 10-day study was 0.13 µg/m^3. The Illinois report noted that air Pb concentrations were elevated downwind of O'Hare airport compared with upwind levels (Illinois Environmental Protection Agency, 2002). Carr et al. (2011) also noted elevated downwind Pb concentrations when studying Pb concentrations at the Santa Monica Airport and surrounding neighborhood in Santa Monica, CA in 2009. The downwind location was higher than upwind (winter: 0.040 µg/m^3 versus 0.0075 µg/m^3; summer: 0.049 µg/m^3 versus 0.0040 µg/m^3). Summer measurements also included a residential neighborhood 100 meters further downwind, which were still higher than upwind (0.033 µg/m^3 versus 0.004 µg/m^3) Modeling results from Carr et al. (2011) also suggest that three-month average Pb concentrations above local background extended beyond the airport property and that the preflight runup check, taxi, and takeoff emissions were the most important contributors to Pb concentrations. This airport had a Pb

emissions inventory of 0.3 tons/year (U.S. EPA, 2011a), which is below the threshold for airports for requiring consideration of Pb NAAQS compliance monitoring (see Section 3.4.2).

Airborne Pb at Urban and Rural Sites

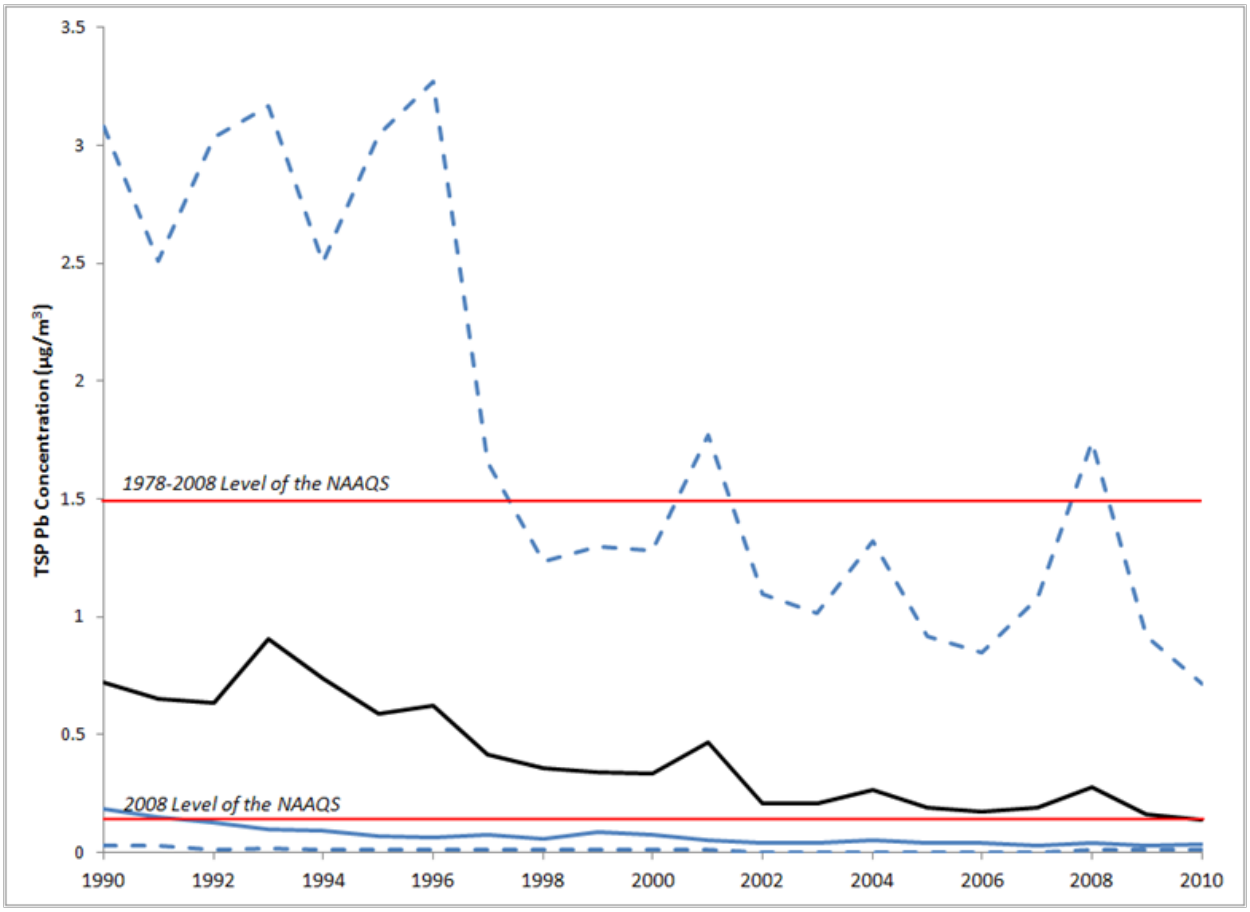
A number of studies characterizing airborne Pb-bearing PM distribution at the neighborhood scale suggest that spatial variability in Pb concentrations is related to local sources. Yu et al. (2011) measured Pb-PM_{10} concentration using a four-channel PM sampler (Thermo Scientific) at four roof-top sites (10-13 meters AGL) within Paterson, NJ: (1) background, (2) near-road (within 0.8 km of two major roads), (3) industrial (within 1 km of three metal processing facilities), and (4) commercial. Coefficient of variation (CV), defined as the standard deviation of site measurements divided by the average) was 31.3%, with concentrations ranging of 5.61 ng/m^3 (near road), 6.48 ng/m^3 (industrial), and 6.58 ng/m^3 (commercial), compared with 2.95 ng/m^3 at the background site. Harrison and Yin (2010) also noted that median urban background Pb concentrations were elevated compared with rural background (urban: 13.9 ng/m^3; rural: 8.0 ng/m^3). Martuzevicius et al. (2004) examined the spatial variability of Pb-$PM_{2.5}$ samples obtained in the greater Cincinnati, OH area at 6 urban, 4 suburban, and 1 rural site using Harvard $PM_{2.5}$ Impactors. They found that Pb-$PM_{2.5}$ had a CV of 33.8%, compared with a CV for $PM_{2.5}$ of 11.3% over all sites. Average Pb-$PM_{2.5}$ concentration among the sites varied from 1.79-28.4 ng/m^3. Martuzevicius et al. (2004) suggested that differences between mass and Pb spatial variability implied that Pb originated primarily from local sources. Sabin et al. (2006a) measured Pb-PM with a Noll Rotary Impactor having an upper cutpoint of 29 μm and found that urban concentrations ranged from 2.2 to 7.4 ng/m^3 with a CV of 40%. In contrast, a rural location had a concentration of 0.62 ng/m^3. Li et al. (2009a) collected $PM_{2.5}$ with a Harvard Impactor and observed that Pb concentration in $PM_{2.5}$ samples was 2.2-3.0 times higher near a bus depot than next to a rural-suburban road; in this study, the authors provided ratios but not actual concentrations. Ondov et al. (2006) measured Pb-$PM_{2.5}$ concentration at three Baltimore sites using an FRM. Average Pb-$PM_{2.5}$ concentrations at the different sites were 8.3 ng/m^3, 7.2 ng/m^3, and 1.9 ng/m^3, with the two higher concentration sites located within two miles of industrial facilities. The industrial sites include a major steel plant; several chemical manufacturing plants; and incinerators for municipal waste, medical waste, and sludge. Although these concentrations are low, they agree with the body of literature to suggest that intra-urban variability is most strongly related to source type, strength, and location.

3.5.2 Temporal Variability

The following sections present data for multi-year trends and seasonal variability of Pb concentrations on a nationwide basis. The data presented here provide information on the success of Pb reduction efforts over past decades as well as on areas for continued attention with respect to Pb monitoring. The multi-year trends illustrate changes in air Pb concentrations resulting from the phase-out of leaded gasoline for automobiles and smaller reductions of industrial Pb usage. The seasonal variability plots demonstrate changes in concentration within a given year, potentially related to climate or source variation.

3.5.2.1 Multi-year Trends

Pb-TSP concentrations have declined substantially during the years 1980-2010. For source and non-source monitors combined in the trends network, the annual average of the maximum 3-month averages across 74 Pb-TSP monitors reporting air Pb concentrations over the period from 1980-2010 has dropped by 89% from 1.3 $\mu g/m^3$ in 1980 to 0.14 $\mu g/m^3$ in 2010 (n = 31); see Figure 3-21. The median maximum 3-month average concentration has declined by 97% from 0.87 $\mu g/m^3$ in 1980 to 0.03 $\mu g/m^3$ in 2010. The decline can be attributed to the phase-out of Pb antiknock agents in on-road fuel and reductions in industrial use and processing of Pb, as described in Section 3.2.1. Average concentrations in these calculations are heavily influenced by the source-oriented monitors in the network.



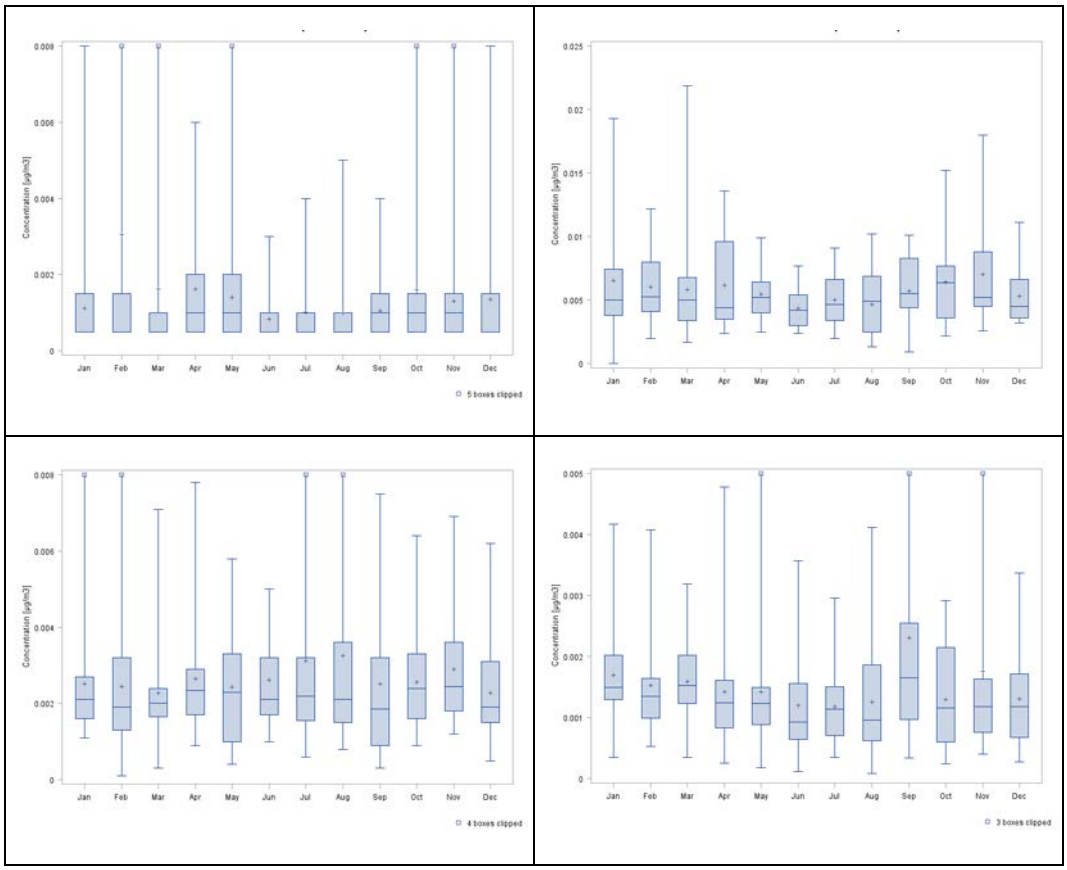
Note: Annual average of maximum 3-month average Pb-TSP concentrations is shown by the solid black line, annual median of maximum 3-month average concentrations is shown by the solid blue line, and the 10th and 90th percentiles are shown by the dashed lines.

Figure 3-21 National trends in Pb concentration (µg/m^3), 74 trends sites, 1990-2010.

3.5.2.2 Seasonal Variations

This section outlines seasonal variability among Pb monitors. Seasonal variation may provide insight related to differential influences of sources and climate throughout a year. Figure 3-22 illustrates average monthly trends in Pb-$PM_{2.5}$ at four IMPROVE sites: Lake County, CA (060333010), Bronx County, NY (360050110), Monroe County, NY (360551007), Chittenden, VT (500070007). In each plot, some month-to-month variability is evident. Seasonal trends, with peaks in median,75th, and 95th percentiles in the spring and fall, are apparent in the Bronx and Chittenden sites. Variability in the median values is less pronounced. These sites do not illustrate national trends, but they do collectively suggest that there can be seasonal variation in ambient air Pb concentration

within sites consistent with findings from the 1970s and 1980s (U.S. EPA, 1986a). National trends in monthly concentrations, provided in the Chapter 3 Appendix (in Figure 3-58, Figure 3-59, Figure 3-60, and Figure 3-61), do not illustrate variability because inter-site variability is averaged out.



Notes: Data were not available for all years at all sites. IMPROVE sites were chosen where at least three years of data were available during 2001-2011. Boxplots are clipped at all but the Bronx site to improve illustration of the variability among the monthly interquartile ranges.

Legend: Top left panel: Lake County, CA 060333010, Top right panel: Bronx County, NY 360050110, Bottom left panel: Monroe County, NY 360551007, and Bottom right panel: Chittenden, VT 500070007.

Figure 3-22 Boxplots of average monthly Pb-$PM_{2.5}$ concentrations measured at four IMPROVE sites, 2001-2010.

Other data regarding seasonal variability of ambient air Pb concentrations have been limited. Laidlaw et al. (2012) also explored the seasonal variability of Pb-$PM_{2.5}$ at four cities (Birmingham, AL, Chicago, IL, Detroit, MI, and Pittsburgh, PA) using data from the Interagency Monitoring of Protected Visual Environments (IMPROVE) network. They observed a strong seasonal pattern with elevated Pb-$PM_{2.5}$ levels in the summer compared with the winter for all four cities. Likewise, Harrison and Yin (2010) observed

that winter background concentrations of Pb were 88% and 81% of summer background concentrations for urban and rural settings, respectively. In addition to the data presented above, monthly average Pb concentrations averaged across sites from the TSP, NATTS, and CSN networks are provided in the Chapter 3 Appendix (Section 3.8.3).

3.5.3 Size Distribution of Pb-Bearing PM

The diverse nature of the main source types of ambient air Pb contributes to variations in Pb-PM size distribution. Such variation in the size distribution, along with size-dependent biases in Pb-TSP collection efficiency (Section 3.4.1.1), can lead to uncertainties in the interpretation of results from Pb-PM measurements. Accordingly, depending on the locations and magnitudes of nearby sources, ambient air Pb may be 1) mainly Pb in PM_{10} and $PM_{2.5}$, for which good sampler performance is well established, 2) Pb-PM with a size distribution that ranges up to slightly larger than 10 µm, in which case the existing Pb-TSP FRM could potentially be subject to wind related bias, or 3) a Pb-PM size range that extends well above 10 µm, or too large to be efficiently collected even by an improved Pb-TSP method. In the latter case, air sampling is likely to be less representative of actual concentrations of Pb. The role of ambient air Pb size distribution on human exposure, along with the role of the size distribution of Pb in soil and dust, is described in Section 4.1.1.1.

Because atmospheric lifetime is dependent on particle size, as described in Section 3.3.1.3 and in the U.S. EPA 2009 PM ISA (2009a), TSP sampling is likely to be representative only on a very small spatial scale. Ultra-coarse particles have a sharp concentration gradient with distance from source, because coarser particles have greater settling velocities. Hence, concentrations of particles larger than 10 µm are likely to be very spatially and temporally heterogeneous compared with finer particles (U.S. EPA, 2009a; Hinds, 1999). As a consequence, in locations near sources of ultra-course particles, measurements may reflect true concentrations only in small areas in close proximity to the monitor. This issue has been thoroughly discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), as well as in the 1977 Pb AQCD (U.S. EPA, 1977).

Size-selective monitoring data from AQS and the literature are examined in this section. Size distribution data enhances understanding of the relationship between sources and characteristics of airborne Pb-bearing PM and hence informs monitoring strategies. Several studies in the literature since the last review have been designed to characterize the size distribution of Pb concentrations in the vicinity of sources. In the following subsections, the currently available information is presented for locations in the vicinity

of industrial sources (active and closed), near roadways, and in other urban and rural environments.

3.5.3.1 Co-located Monitoring Data Analysis

This section employs AQS data for Pb concentrations from co-located TSP, PM_{10}, and/or $PM_{2.5}$ monitors to analyze correlations and ratios of concentrations obtained from the different monitors. These data were used because relationships among the monitors provide information about the nature of Pb-bearing PM at different locations (e.g., whether the mode is in the fine or coarse fraction). Correlations indicate the extent to which the size fractions vary together in time, and ratios signify the average proportion of the smaller fraction to the larger fraction (e.g., the ratio of $PM_{2.5}$ to PM_{10} concentrations).

Estimation of the size distribution of Pb-bearing PM is possible at a limited number of monitoring sites where monitors having different size-selective cut-points are co-located. Data for correlations between concentrations at co-located monitors having different size cuts and average ratios of concentrations from these co-located monitors are available per co-location site in Table 3-26 in the Chapter 3 Appendix (Section 3.8), and a summary of these data are provided in Table 3-8. To ensure quality of the comparisons, data from co-located monitoring pairs are presented if there were at least 30 co-located data points, the data from both monitors were above the MDL, and data from both monitors were presented at standard temperature and pressure.

The collective size cut comparison data illustrate that the correlations and concentration ratios of Pb-TSP with the Pb-PM_{10} and Pb-$PM_{2.5}$ fractions are moderate, with less correspondence of Pb-$PM_{2.5}$ with Pb-TSP compared with Pb-PM_{10}. The findings indicate that, on average, 81% of Pb-TSP is in the Pb-PM_{10} fraction, and 50% is in the Pb-$PM_{2.5}$ fraction, and 74% of the Pb-PM_{10} was in the Pb-$PM_{2.5}$ fraction (assuming no bias in the Pb-PM measurements, which may not be a reasonable assumption based on Section 3.4.1). However, for co-located pairs of Pb-TSP with Pb-PM_{10} or Pb-$PM_{2.5}$, the ranges of correlations and ratios were large, indicating substantial spatiotemporal variability. There appeared to be little difference between urban and suburban correlations and concentration ratios. For three co-located Pb-PM_{10} :Pb-TSP pairs in Wichita, KS, the average concentration ratios greater than one were observed. This suggests that some portion of the particles captured by the PM_{10} sampler were not collected by the TSP sampler, perhaps as a result of instrument biases, as discussed in Section 3.4.1. Likewise, if such a bias is consistent across monitors, it is possible that, even for average ratios less than one, the average ratios would be lower if the particles were sampled more efficiently with the TSP monitor.

Table 3-8 Summary of comparison data for co-located ambient air Pb monitors.

Monitors*	Correlation				Average Ratio		
	N	Average	Standard Deviation	Range	Average	Standard Deviation	Range
All Sites							
Pb-PM_{10} vs. Pb-TSP	36	0.74	0.23	0.13-0.99	0.81	0.19	0.38-1.28
Pb-$PM_{2.5}$ vs. Pb-TSP	20	0.62	0.28	0.11-0.96	0.50	0.12	0.30-0.73
Pb-$PM_{2.5}$ vs. Pb-PM_{10}	28	0.91	0.12	0.50-0.99	0.74	0.06	0.59-0.90
Urban and City Center							
Pb-PM_{10} vs. Pb-TSP	18	0.76	0.20	0.40-0.99	0.80	0.12	0.57-0.99
Pb-$PM_{2.5}$ vs. Pb-TSP	12	0.58	0.31	0.11-0.96	0.50	0.09	0.36-0.62
Pb-$PM_{2.5}$ vs. Pb-PM_{10}	14	0.89	0.15	0.50-0.99	0.74	0.06	0.69-0.90
Suburban							
Pb-PM_{10} vs. Pb-TSP	18	0.73	0.26	0.13-0.96	0.81	0.25	0.38-1.28
Pb-$PM_{2.5}$ vs. Pb-TSP	8	0.69	0.22	0.31-0.91	0.51	0.15	0.30-0.73
Pb-$PM_{2.5}$ vs. Pb-PM_{10}	12	0.92	0.08	0.74-0.99	0.73	0.07	0.59-0.82

*Note: For comparability, comparisons are limited to monitors where all samples were above the MDL, at least 30 co-located samples were obtained, and both monitors reported data at standard temperature and pressure. N: sample size, PM: particulate matter, TSP: total suspended particulate matter.

3.5.3.2 Studies of Pb-bearing PM Size Distribution in the Literature

The size distribution of Pb-bearing PM has changed over time and by site. Table 3-9 is reproduced from Cho et al. (2011), which reviewed studies of the size distribution of Pb-bearing PM. Studies included in Cho et al. (2011) from the late 1960s to the early 1980s reported substantially higher Pb concentrations compared with current levels. Traffic-related emissions produced higher contributions from Pb-$PM_{2.5}$ compared with industrial emissions. More recent studies from the 1990s and 2000s illustrated variability in the size distribution regardless of whether the source was traffic or industrial. Cho et al. (2011) concluded that the size distribution appears to have shifted after the 1980s, with the mode appearing to fall somewhere between 2.5 μm and 10 μm, compared with previous estimations of a primary mode smaller than 2.5 μm; however, Cho et al. (2011) maintained that additional data are needed to improve characterization of the Pb-PM size distribution. Metadata and size distribution data from cited studies are provided in Table 3-27 and Table 3-28, respectively, of the Chapter 3 Appendix (Section 3.8).

Table 3-9 Summary of studies reporting Pb size distribution in the peer-reviewed literature.

Airborne Pb near Metals Industries

Differences among size distributions have been noted for studies contrasting industrial and background sites. Yi et al. (2006) collected Pb-PM size distribution in an industrial area of Jersey City, NJ and contrasted it with the Pb-PM size distribution in suburban New Brunswick, NJ, which is influenced only by traffic. Yi et al. (2006) sampled size distribution for Pb-bearing particles with a MOUDI (cut point range: 0.18-18 µm) along with a coarse particle rotary impactor (CPRI) collecting particles ranging in size from 14.4-100 µm. In the industrial area, 27% of Pb-PM were larger than PM$_{10}$ (avg. Pb-TSP: 9.7 ng/m^3), while in the suburban area 7% of Pb-PM were larger than PM$_{10}$ (avg. Pb-TSP: 6.6 ng/m^3). Singh et al. (2002) used a MOUDI to measure the mass distribution of Pb-PM$_{10}$ in the coarse and fine PM size ranges (cut points range: 0.10-10 µm) for the Downey site along the Alameda industrial corridor in Los Angeles, CA and a site approximately 90 km downwind in Riverside, CA. At the industrial site, the Pb-PM$_{10}$ size distribution was unimodal with a concentration peak in the 100-350 nm size range. The sum of the geometric mean concentrations in each size bin was 13 ng/m^3 for the Downey data. At the downwind site, a bimodal distribution was observed with peaks in the 2.5-10 µm bin and the 350 nm-1 µm bin. The sum of the geometric mean concentrations in each size bin was 7 ng/m^3 for the Riverside data. The authors suggested that higher wind speeds in Riverside compared with the Downey site are effective in resuspending larger particles from the ground to create a peak in the coarse mode of the distribution.

Recent studies have indicated temporal variation in the size distribution given differences among wind direction and industrial production. Bein et al. (2006) measured the size distribution of PM containing Pb from the Pittsburgh Supersite using rapid single particle mass spectrometry and a MOUDI. Source apportionment illustrated that Pb was contained in a sub-population of particles of almost every major particle-containing class in this study, emanating from point sources including fuel combustion, steel processing, incinerators, foundries, battery manufacturing, and glass manufacturing (Pekney et al., 2006). Bein et al.'s (2006) measurements yielded different results on different days, with a bimodal distribution with modes around 140 nm and 750 nm during an October, 2001 measurement and a single dominant mode around 800 nm during a March, 2002 measurement. Differences in the size distributions could have been related to differences among wind speed, wind direction, and source contributions on the respective dates. Weitkamp et al. (2005) used a HI-VOL sampler to measure Pb-bearing $PM_{2.5}$ concentrations across the river from a coke plant in the Pittsburgh, PA area and analyzed the data with ICP-MS. Pb comprised 0.088% of the $PM_{2.5}$ mass, and the mode of the size distribution (measured overall but not specifically for Pb) was observed to shift between 50 nm to 1 μm. Dall'Osto et al. (2008) used a MOUDI (cut points range: 0.196-18 μm) to measure the size distribution of Pb emissions from a steel works facility in a coastal town within the United Kingdom (U.K.). The size distribution was multimodal with a primary mode around 1 μm, a secondary mode around 300 nm, and a very small additional mode around 5 μm. This multimodal distribution was thought to be associated with sintering and steel working processes, from which Pb was emitted. Pekey et al. (2010) measured $PM_{2.5}$ and PM_{10} concentrations in a heavily industrialized area of Kocaeli City, Turkey using a low-volume PM_{10} stack filter unit. They observed $PM_{2.5}/PM_{10}$ ratios of 0.60 during summer and 0.45 during winter.

Airborne Pb Near Roadways

Traffic-induced turbulence may be a cause of resuspension of Pb-bearing particles from deposited contemporaneous wheel weights, industrial emissions, or historic sources. Pb mass in near-road PM is predominantly associated with the coarse mode (U.S. EPA, 2006b). The Pb fraction in resuspended dust generally ranges from 0.002 to 0.3%, with the highest fractions observed for paved road dust and lowest for agricultural soil. Sabin et al. (2006b) compared the size distribution of coarse Pb-PM measured using a Noll Rotary Impactor at an urban background site and at a location 10 meters from the I-405 Freeway in the southern California air basin; data from Sabin et al. (2006b) are displayed in Figure 3-23. For both the urban background and near-road sites, the largest fraction was from PM sampled below the 6 μm cut point, but the near-road Pb-PM distribution appeared bimodal with a mode in the largest size fraction. Sabin et al. (2006b) point out

that the freeway tends to be a source of very large particles that are dispersed via the turbulent motion of the vehicular traffic. Song et al. (2011) used an eight-stage MOUDI (cut point range: 0.18-18 µm) to measure roadside PM, 5 meters from the New Jersey Turnpike in Carlstadt, NJ and speciated the samples. They observed a bimodal distribution of the Pb concentration in summer and a trimodal distribution in winter. 85% of the Pb-PM mass was measured as $PM_{2.5}$ during the summer, and 68% was measured as $PM_{2.5}$ in the winter. Similarly, Zereini et al. (2005) observed that roughly 80% of particle-bound Pb measured with a MOUDI was smaller than 5.8 µm for an urban main street, and more than 90% were smaller than 5.8 µm for a rural area included in that study. However, in a study of automotive emissions in a traffic tunnel, Lough et al. (2005) observed that 85% of Pb measured with a MOUDI was in the PM_{10}, with just 39% in the $PM_{2.5}$ fraction and 20% in the PM_1 fraction. In a near-road study conducted in Raleigh, NC with a 13-stage low-pressure impactor, Hays et al. (2011) note that the proportion of Pb within particles in ultrafine, fine, and coarse size ranges was the same at 50 mg/kg; similar to Lough et al. (2005), mass concentrations were measured by Hays et al. (2011) to be 0.4 ± 0.4 ng/m^3, 1.4 ± 0.6 ng/m^3, and 0.1 ± 0.02 ng/m^3 for $PM_{10-2.5}$, $PM_{2.5-0.1}$, and $PM_{0.1}$, respectively. The Pb-PM_{10} samples from Hays et al. (2011) were highly correlated with As samples ($\rho = 0.7$, $p < 0.0001$); both Pb and As are found in wheel weights (see Section 3.2.2.6). Hays et al. (2011) did not report correlations between Pb and As for smaller size fractions, but they did state that the correlations for other size fractions were lower compared with Pb-PM_{10} and As. Likewise, the Pb samples were not well correlated with crustal elements in the coarse size distribution, so it is more likely that resuspended Pb originated from contemporary roadway sources rather than historic Pb on-road gasoline emissions. Chen et al. (2010b) measured Pb in $PM_{10-2.5}$, $PM_{2.5-0.1}$, and $PM_{0.1}$ using a MOUDI at a roadside location and in a tunnel in Taipei, Taiwan in 2008. While roadside and tunnel concentrations of PM_{10} and $PM_{2.5}$ were roughly equivalent around 20-30 ng/m^3, Pb in $PM_{0.1}$ was approximately 15 times higher in the tunnel (during the hours 9:00 a.m. – 9:00 p.m.) than by the roadside (tunnel: 20 ng/m^3; roadside: 1 ng/m^3). The authors suggest that particle-bound Pb was emitted from on-road gasoline and diesel engines. This could possibly be attributed to trace levels of Pb in diesel fuel and lubricating oil. Birmili et al. (2006) compared concentrations of Pb in PM measured with a Sierra-Anderson high volume cascade impactor at various traffic and background sites in Birmingham, U.K. Birmili et al. (2006) captured PM at the stage below a 0.5 µm cutpoint and on the 1.5-3.0 µm stage for near-road, in a traffic tunnel, and remote and urban background sites. The highest concentrations were measured in the tunnel, at 3.3 ng/m^3 for Pb-$PM_{0.5}$ and 10 ng/m^3 for Pb-$PM_{1.5-3.0}$. In contrast, urban background was more enriched in the finer size fraction, with concentrations of 5.4 ng/m^3 for Pb-$PM_{0.5}$ and 0.84 ng/m^3 for Pb-$PM_{1.5-3.0}$. Remote background concentrations were on 0.16 ng/m^3 for Pb-$PM_{0.5}$ and 0.03 ng/m^3 for Pb-$PM_{1.5-3.0}$. Bruggemann et al. (2009) measured

roadside distribution of Pb in PM in Dresden, Germany using a 5-stage Berner-type low-pressure impactor to analyze the effect of season and direction of the air mass. For all data combined as well as for data broken down by season or by wind direction, it was found that the data followed a unimodal distribution with a peak at the 0.42-1.0 µm size bin with roadside measurements averaging 13-22 ng/m^3, depending on wind direction. Evidence of Pb in road dust related to near road ambient air Pb concentrations is described in Section 3.6.1.

Figure 3-23 Comparison of urban background and near-road size fractions of Pb-bearing PM.

Several studies have suggested that near-road ambient air Pb samples are derived from sources other than from the road. Harrison et al. (2003) measured the distribution of Pb in PM_{10} at a roadside sampler in Birmingham, U.K. using a MOUDI fitted with only stages 1, 2, 4, and 8 with cutpoints of 10 µm, 2 µm, 1 µm, and 0.2 µm. The size distribution was unimodal with approximately 2% of the Pb mass (totaling 26.5 ng/m^3) above the 10 µm cut point, 12% of the mass in the 2-10 µm bin, 8% in the 1-2 µm bin, 53% of the Pb mass in the 0.2-1 µm bin, and 25% collected below the 0.2 µm cut point. Regression analysis against NO_X concentration in the Harrison et al. (2003) paper provided a weak indication that Pb-$PM_{0.2}$ was associated with NO_X ($\beta = 0.067$, $R^2 = 0.38$) as well as PM_{10} ($\beta = 0.26$, $R^2 = 0.35$). Brüggemann et al. (2009) observed a unimodal Pb size distribution with 51% of the mass in the 0.42-1.2 µm size bin. Observed Pb-PM_{10} concentration was 17 ng/m^3. During winter, Pb concentrations were more than twice as high as during the summer (winter: 24 ng/m^3; summer: 10 ng/m^3), and they were also higher when winds blew from the east (0.42-1.2 µm mode, east: 60 ng/m^3; west: 25 ng/m^3). Brüggemann et al. (2009) suggested that this finding reflected coal burning sources dominating Pb emissions rather than road dust resuspension during winter. Wang et al. (2006d) used a nine-stage cascade impactor (cut point range: 0.43-11 µm) to measure the Pb-PM size distribution in a heavily trafficked area of Kanazawa, Japan with incineration and generation facilities nearby. They observed a bimodal distribution with modes at the 0.65-1.1 µm and the 3.3-4.7 µm size bins. Average concentration in the coarse mode was 2.1 ng/m^3, while fine-mode average concentration was 3.7 ng/m^3. Wang et al.'s (2006d) source apportionment work in this study suggested that the fine mode derives from incineration and combustion of oil and coal.

Airborne Pb at Other Urban and Rural Sites

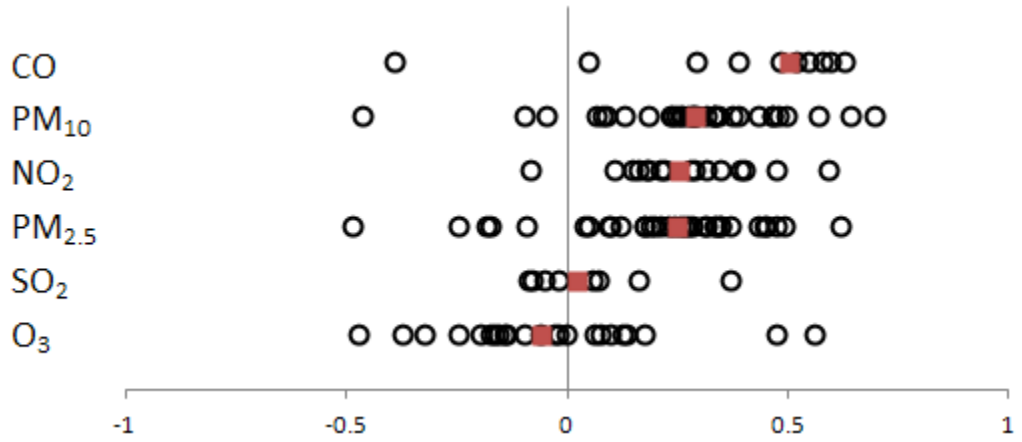
Spatial and temporal concentration variability is also reflected in varying Pb-PM size distributions within and between cities. Martuzevicius et al. (2004) measured the size distribution of Pb in Cincinnati, OH at the city center site using a MOUDI and showed it to be bimodal with a primary peak at 0.56 µm and a slightly smaller secondary peak at 5.6 µm. Using high volume samplers, Moreno et al. (2008) measured Pb concentrations in $PM_{2.5}$ and PM_{10} at urban, suburban, and rural sites around Mexico City, Mexico to illustrate differences among the land use categories. At the urban site, $PM_{2.5}/PM_{10}$ ratios were 0.51 during the day and 0.57 at night (Pb-PM_{10} was 59 ng/m^3 and 162 ng/m^3, respectively). At the suburban site, Pb-$PM_{2.5}$/Pb-PM_{10} ratios were 0.63 during the day and 0.81 at night (Pb-PM_{10} was 24 ng/m^3 and 42 ng/m^3, respectively). Goforth and Christoforou (2006) measured Pb-TSP and Pb-$PM_{2.5}$ with a high volume cyclone separator in rural Georgia and observed a Pb-$PM_{2.5}$ concentration of 6 ng/m^3 and a Pb-TSP concentration of 15 ng/m^3. Makkonen et al. (2010) measured concentrations of

Pb-PM_1, Pb-$PM_{2.5}$, and Pb-PM_{10} during a spate of wildfires in rural southeastern Finland with high volume size-selective samplers. They found that the ratio of Pb-PM_1/Pb-PM_{10} varied substantially from day to day (examples provided of 64% on 8/14/07 and 35% on 8/25/07, with Pb-$PM_{2.5}$/Pb-PM_{10} ratio of 51% on 8/25/07), and they attributed the highest concentrations to long-range transport of wildfire emissions via southerly winds; variability in concentration and ratios was related to shifting wind conditions.

3.5.4 Pb Concentrations in a Multipollutant Context

The correlations between Pb and copollutant concentrations were investigated because correlation may indicate commonality of sources among the pollutants. For example, correlation between Pb and SO_2 may suggest common industrial sources. Correlation between Pb and NO_2 or CO may suggest roadway sources, such as trace Pb in unleaded on-road gasoline or resuspension of material from pulverized wheel weights or contaminated soil. Additionally, seasonality can influence correlations, potentially from differences among sources or the contaminants' responses to climate differences.

Pb concentrations exhibit varying degrees of association with other criteria pollutant concentrations. At most sites, Pb monitors are co-located with monitors for other criteria pollutants, but monitoring the full suite of criteria pollutants at a single monitoring site is rare. As a result, the number of observations for each copollutant varies. Pearson correlations of monitored non-source Pb-TSP concentrations with concentrations of other criteria pollutants are summarized in Figure 3-24 for 2008-2010 data for 46 Pb-TSP monitors at which data were above MDL and more than 30 data pairs were measured at each point. Seasonal co-pollutant measurement data from the literature are also provided in the Chapter 3 Appendix (see Figure 3-63 through Figure 3-67).



Note: Correlations were calculated from available data when data were above MDL and there were at least 30 data pairs available for comparison. Number of data pairs for each pollutant varies as follows: CO: 10, PM_{10}: 34, $PM_{2.5}$: 34, SO_2: 9, O_3, MDL for Pb varied with sampling conditions; median MDL = 0.0075 µg/m^3. MDL: O_3: 5 ppb, SO_2: 2 ppb, NO_2: 5 ppb, CO: 0.5 ppm, PM_{10}: 4 µg/m^3, $PM_{2.5}$: 2 µg/m^3.

Correlations for individual sites are shown with black open circles, while median correlations are illustrated with a red square.

Figure 3-24 Pearson correlations of monitored non-source daily average Pb-TSP concentration with daily averages of copollutant concentrations, 2008-2010.

Overall, non-source Pb-TSP was most strongly associated with CO (median R = 0.51), with positive Pearson correlation coefficients observed at all but one site, followed by $PM_{2.5}$, and PM_{10} (median R = 0.31 and 0.28, respectively). The relatively high correlations between Pb-TSP and CO may suggest common combustion sources affecting the pollutants. Mobile sources are the largest contributors of CO emissions (U.S. EPA, 2010). However, given that Pb emissions are no longer from tailpipes, correlations may be related to other on-road Pb emissions, such as tire weights. Alternately, the higher correlation with CO could reflect coincident levels of traffic and occurrence of Pb emissions from various sources such as fossil fuel combustion or piston-engine aircraft emissions. Overall correlation coefficients between Pb and NO_2 and between Pb and SO_2 were also positive at most sites, but associations were generally weaker (median R = 0.22 for NO_2, 0.10 for SO_2). The poorest associations were observed between Pb and O_3 (median ρ = -0.04). Spearman correlations, illustrated in Figure 3-62 in the Chapter 3 Appendix, were similar in magnitude and direction with the exception of $PM_{2.5}$, which had a slightly lower median Spearman correlation than both PM_{10} and NO_2.

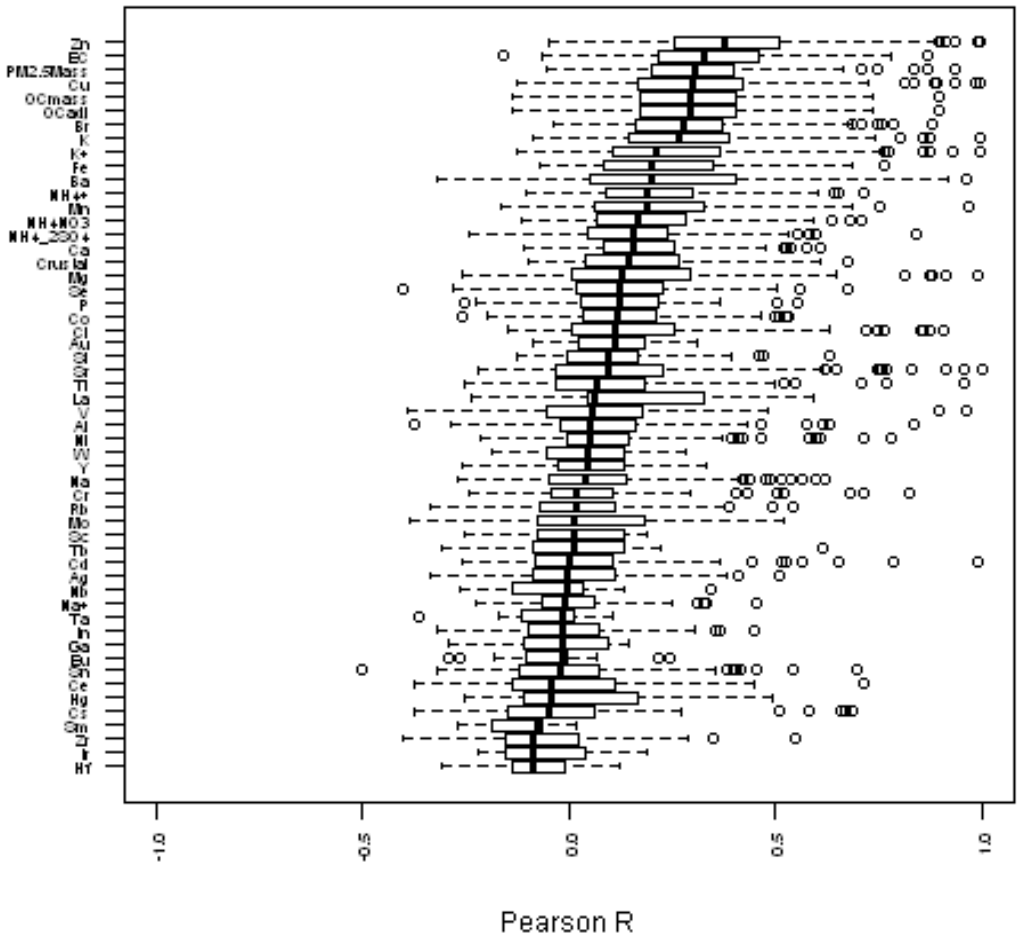
The relationship between Pb and other species in $PM_{2.5}$ is explored in Figure 3-25, which describes data from 2008-2010 CSN results using Pearson R. These data provide a national perspective on relationships between the various bulk and elemental species monitored in the CSN network. Correlations were only obtained when the data were above MDL and at least 30 data pairs were available.

Associations between Pb-$PM_{2.5}$ and other species were generally low-to-moderate. The strongest association was with zinc (Zn) (median R = 0.38). Elemental carbon (EC), $PM_{2.5}$ mass, copper (Cu), organic carbon (OC) mass, and bromine (Br) also exhibited low-to-moderate associations with Pb-$PM_{2.5}$ concentrations (median R = 0.28 to 0.33). Such correlations may suggest some common sources affecting the pollutants, as described in Section 3.2.2. For example, correlation with EC and OC mass may be diagnostic indicators of some crustal, general combustion, industrial emission, and coal combustion processes. Piston-engine aircraft emit Pb as $PbBr_2$ so this source may explain the weak covariation in Pb and Br concentrations at the CSN sites. At the same time, these species must have other disparate sources that drive the Pearson correlations down.

A few recent studies have used speciation techniques to characterize Pb and other components of PM_{10}, $PM_{2.5}$, and PM_1. Pingitore et al. (2009) used XAFS to speciate air samples obtained near a defunct smelter in El Paso, TX, in 1999 and 2005 and found that air Pb-TSP concentrations of 0.10 to 0.50 $\mu g/m^3$ could largely be attributed to Pb-humate. Similarly, Laidlaw et al. (2012) observed statistically significant associations between ambient air Pb-$PM_{2.5}$ and ambient air soil in Pittsburgh, PA, Chicago, IL, Detroit, MI, and Birmingham, AL (R^2 = 0.31-0.49, p <0.01). Together, these results suggest a link between soil resuspension and Pb-TSP levels

Murphy et al. (2008) studied weekly patterns of metals and other aerosol components using data collected from 2000 to 2006 at IMPROVE sites. The authors concluded that Pb concentrations were impacted by piston aircraft emissions. They reached this conclusion because, in contrast to other species, Pb was elevated on weekends when there is typically a peak in general aviation flights. The authors also note that Zn and Pb were highly correlated in atmospheric samples, and they suggest that this is due to similar sources (i.e., electric utility and industrial sources). Murphy et al. (2007) also carried out a detailed study of the distribution of Pb in single atmospheric particles. During the fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere (CLACE 5) campaign conducted at the Jungfraujoch High Altitude Research Station, Switzerland, about 5% of analyzed aerosol particles in PM_1 contained Pb. Of these, 35% had a relative signal for Pb greater than 5% of the total mass spectrum measured by an aerosol time of flight mass spectrometer (ATOFMS). These “high Pb” particles also contained one or more positive ions (e.g., of Na^+, Mg^{2+}, Al^{3+}, K^+, Fe^{3+}, Zn^{2+}, Mo^{6+}, Ag^+, Ba^{2+}). Sulfate fragments were present in 99% of the negative ion spectra associated with high Pb particles, and 50% also contained nitrite and nitrate. About 80% contained positive and/or negative polarity organic fragments. The average aerodynamic diameter of the Pb-rich particles (500 nm) was larger than the background aerosol (350 nm) but none had a diameter less than 300 nm. Murphy et al. (2007) suggest that this mixture can be

attributed to combined emissions from combustion (e.g., Pb and organics) and industry (e.g., Pb sulfates).



Note: Correlations were calculated from available data when data were above MDL and there were at least 30 data pairs available for comparison; organic carbon (OC) samples were blank-adjusted.

Figure 3-25 Pearson correlations of monitored Pb-$PM_{2.5}$ concentration with copollutant concentrations, 2008-2010.

3.5.5 Background Pb Concentrations

The 2006 and 1986 Pb AQCDs evaluated evidence on Pb emissions from natural sources, such as volcanoes, sea-salt spray, biogenic sources, wild forest fires and wind-borne soil particles in rural areas without elevated Pb soil concentration. The 1986 Pb AQCD concluded that the natural particulate Pb concentration was probably lower than the concentration of 0.076 ng/m^3 reported at the South Pole (U.S. EPA, 1986a). A 1980 National Academy of Sciences (NAS) report estimated that average natural background levels of airborne Pb might range from 0.02 to 0.5 ng/m^3 (NAS, 1980).

Global transport can carry airborne Pb to remote areas with no industrial activity, thus it is difficult to estimate a natural background concentration of Pb. Hong et al. (1994) found that Pb concentrations in Greenland ice cores remained nearly constant (at about 0.55 pg Pb/g ice) from about 7,760 years ago to about 3,000 years ago. Ratios of Pb to major crustal elements were not enriched compared with natural background levels in this section of the ice core suggesting that Pb was natural in origin, produced by rock and soil dust. At about 2,500 years ago, Pb concentrations started to increase (to about 100 pg Pb/g snow averaged from 1930 to 1990) (Boutron et al., 1991) corresponding to an enrichment of ~200 times natural background levels. McConnell and Edwards (2008) also noted elevated Pb levels in Greenland ice cores, with high correlation to black carbon (BC), cadmium (Cd), sulfur (S), and thallium (Tl) during the period 1860-1940, suggesting coal combustion sources from North America. Osterberg et al. (2008) observed elevated Pb levels in a 1970-1998 ice core from Mt. Logan, Canada, indicating elevated Pb levels corresponding to increased industrial activity in Asia during this time period.

Measurements of Pb from IMPROVE sites and source apportionment modeling have been used to assess the potential input from intercontinental transport. Liu et al. (2003) used positive matrix factorization to attribute sources of Asian dust to the measurements at two western IMPROVE sites at high elevations, Crater Lake (Oregon) and Lassen Volcanic Park (California) from 1988 to 2000. Geometric mean Pb concentrations of 0.34 and 0.48 ng/m^3 were found in the samples with only a few percent of these values attributable to transport from Asia. No enrichment in Pb and other metals (As, Cr, Cu, Ni, Pb, V and Zn) above reference Asian-dust material was found. Their results suggest either that arriving air masses did not entrain contributions from Asian pollution sources or that these contributions were preferentially scrubbed out during transport. Large enrichments in sulfur (S) were found, however, which might have been due to pollution sources but also due to model artifacts. However, other studies have found some evidence of trans-Pacific transport. Murphy et al. (2007) measured single Pb particles off the coast of California (using a National Oceanic and Atmospheric Administration [NOAA]

aircraft elevated more than 2 km above ground level). Given the elevation of the measurement and the timing of trans-Pacific plume events, the authors concluded that these Pb-bearing $PM_{2.5}$ originated in Asia. They also noted Pb/Zn ratios in $PM_{2.5}$ at the Mount Zirkel, CO IMPROVE site of 0.6 corresponding to measurements at Mauna Loa, HI in spring, when measurements at other times of year produced Pb/Zn ratios of 0.3-0.4. Ewing et al. (2010) used time series analysis of Pb isotope measurements to estimate Asian and local contributions to Pb-$PM_{2.5}$ concentrations measured at two observatories near San Francisco, CA. They estimated a springtime contribution of Asian dust to Pb-$PM_{2.5}$ measurements. In both the Murphy et al. (2007) and Ewing et al. (2010) studies, the authors conclude that the Asian contribution is still generally less than 1 ng/m^3.

The use of data for $PM_{2.5}$, $PM_{10-2.5}$, and PM_{10} from monitoring sites in the East will generally result in gross overestimates of background concentrations because anthropogenic sources will cause extensive contamination. Intercontinental transport of African dust contributes to PM and is observed mainly in the Southeast but is apparent on an episodic basis elsewhere in the eastern U.S. [see e.g., 2004 PM AQCD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009a)]. Data obtained at four eastern IMPROVE sites ([1] Moosehorn National Wildlife Refuge, ME; [2] Acadia National Park, ME; [3] Swanquarter, NC; and [4] Cape Romain National Wildlife Refuge, SC) from 2007 to 2009 indicate a median Pb-$PM_{2.5}$ concentration of 1.0 ng/m^3 with a 95th percentile value of 2.5 ng/m^3. As noted above, these sites are likely to be affected by upwind anthropogenic sources within the U.S.

Rough estimates for the natural source of Pb in different size fractions of Pb-PM can be made by multiplying the abundance of Pb in soils by the crustal component of PM in the different size fractions. The mean abundance of Pb in surface rocks is ~20 mg/kg (Potts and Webb, 1992); the 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb concentrations in different types of rocks to range from 3.5 to 32 mg/kg (Reuer and Weiss, 2002). There is substantial variation with location depending on composition, in particular on the abundances of uranium (U) and thorium (Th), since Pb is produced mainly by radioactive decay of these elements. The mean Pb concentration of 863 soil samples taken across the U.S. at 2 meters depth is ~16 mg/kg; this value was derived by sampling residual Pb of the weathered rocks on which they formed [Wedepohl (1978) and references therein].

Concentrations of the Pb content of soils can be used with estimates of the crustal component of $PM_{2.5}$, $PM_{10-2.5}$ (which is mainly crustal), PM_{10}, and TSP produced by wind erosion of natural surfaces to estimate contributions to Pb concentrations in these size fractions. U.S. annual average PM_{10} concentrations in some arid counties most affected by windblown dust in the western U.S. are ~20 μg/m^3. If it is assumed that these levels of PM_{10} are entirely due to natural wind erosion without any anthropogenic contribution and

that the Pb concentration in all airborne size fractions if the same as the Pb concentration in bulk soil or surface rock, an estimate of ~0.3 ng/m^3 for the contribution of wind erosion on natural surfaces to Pb in PM_{10} is obtained; however, it must be observed that the natural contribution is probably lower than this estimate. An assumed ratio 3.5 for TSP to PM_{10} in dust storms, derived by Bacon et al. (2011), indicates a contribution of ~1 ng/m^3 for Pb from natural sources in TSP. The more recent estimate indicates that background airborne Pb concentrations are well below current ambient concentrations. These estimates exceed estimates of natural background presented in the 1986 AQCD (U.S. EPA, 1986a) and the National Academy of Sciences Report (NAS, 1980) by a factor of 2 to 50. Hence, a plausible range of natural background airborne Pb is 0.02 to 1 ng/m^3.

3.6 Ambient Pb Concentrations in Non-Air Media and Biota

There have been some major recent research efforts to characterize geographic and temporal trends in Pb concentrations across a variety of environmental media and biota. In general these concentrations reflect the decreases observed in atmospheric Pb concentrations due to reduced on-road Pb emissions.

The 2006 Pb AQCD (U.S. EPA, 2006b) describes several studies showing higher Pb concentrations in plants grown in Pb contaminated soil related to mine spoils, smelting operations, sludge amendment, contaminated irrigation water, and Pb containing agro-chemicals. In general, metal accumulation occurs more readily for Pb salts applied to soils than for the same quantity of metal in sewage sludge or fly ash. Root uptake is the dominant means of accumulation, and it is strongly influenced by pH. Root vegetables are the most strongly affected, and fruits and grains are the least susceptible. More Pb is also generally found in roots than in other parts of the plant.

The 2006 Pb AQCD (U.S. EPA, 2006b) identified ingestion and water intake as major routes of Pb exposure for aquatic organisms, and it identified food, drinking water, and inhalation as major routes of exposure for livestock and terrestrial wildlife. The 2006 Pb AQCD (U.S. EPA, 2006b) reports data from the U.S. Geologic Service National Water-Quality Assessment (NAWQA), which are updated every ten years. In the NAWQA survey, maxima concentrations in surface waters, sediments, and fish tissues were 30 μg/L, 12,000 mg/kg, and 23 mg/kg, respectively, compared with median values of 0.50 μg/L, 28 mg/kg, and 0.59 mg/kg. Some of the highest levels of Pb contamination occur near major sources, like smelters, and fatal doses have been measured in tissue from sheep and horses near sources. High levels in cattle have also been observed. Wildlife in urban areas tend to contain higher Pb concentrations than in rural areas, and

higher Pb accumulations have been observed for aquatic organisms living in polluted coastal zones than in the open sea. Ingestion of deposited Pb-PM on plant surfaces was consistently observed to be more important than Pb accumulated from soil. Some important variations between animals have been observed, and ruminants appear to be less susceptible to Pb uptake than other animals. Uptake of Pb by lowest trophic levels, including invertebrates, phytoplankton, krill, were described as the most important means of introduction into food chains. Elevated Pb levels have been observed in aquatic organisms that feed from sediments when the sediments contain appreciable Pb. In shrimp, a substantial fraction of Pb can be absorbed from prey, and considerably more accumulated Pb from food has been observed to be irreversibly retained than is the case for dissolved Pb from water. These examples all illustrated that substantial Pb uptake by livestock and wildlife readily occurs in Pb contaminated environments.

3.6.1 Soils

Several studies suggest that soil can act as a reservoir for contemporary and historical Pb emissions. The importance of soil Pb to human exposure is described in Section 4.1. At the same time, soils in remote or rural areas tend to have lower Pb concentrations. The most extensive survey of background soil Pb concentration in the conterminous U.S. was conducted between 1961 and 1976 and comprised 1,319 non-urban, undisturbed sample locations, where 250 cm^3 of soil was collected at a depth of 20 cm (Shacklette and Boerngen, 1984). The lower detection limit was 10 mg/kg, and 14% of the 1,319 samples were below it. The mean Pb concentration was 19.3 mg/kg, the median 15 mg/kg, and the 95th percentile was 50 mg/kg. Sixteen locations had Pb concentrations between 100 and 700 mg/kg. These results were in agreement with 3 previous surveys. When creating the *Ecological Soil Screening Level (Eco-SSL) Guidance and Documents*, the U.S. EPA (U.S. EPA, 2007d, 2003b) augmented these data with observations from an additional 13 studies conducted between 1982 and 1997, most of them limited to one state. The resulting data were summarized using state means for each of the fifty states. Those means ranged between 5 and 38.6 mg/kg, with an overall national mean of 18.9 mg/kg. This is reasonably close to the values reported by Wedepohl (1978) and references therein with a mean soil Pb concentration of roughly 16 mg/kg when samples were taken at 2-meter depths. Biasioli et al. (2006) contrasted urban and rural soils (tested at soil depths of 0-20 cm) of the same alluvial composition near Torino, Italy to assess the influence of anthropogenic inputs. The urban soils had a median Pb concentration of 117 mg/kg, while the median Pb concentration for rural soil was 19 mg/kg. Table 3-10 presents data from seven metropolitan areas (Cobb et al., 2006). Differences among the intraurban concentration ranges illustrate a high level of spatial variability within

individual cities as well as high inter-urban variability. The rural New Orleans site reported relatively low Pb soil concentrations, and the highest average Pb soil concentrations were reported for the city of New Orleans.

Table 3-10 Soil concentrations in various cities, prior to 2005.

City	Avg Pb Concentration (mg/kg)[a]	Pb Concentration Range (mg/kg)[a]
Baltimore, MD		1-10,900
Miami, FL	275	25-1,612
Mt. Pleasant, MI	320	100-840
New Orleans, LA	784	31.7-5,195
New Orleans, LA (rural outskirts)	11	4.8-17.3
St. Louis, MO	427	35-1,860
Syracuse, NY	80	20-800

In North American forest soils, Pb concentrations have decreased substantially since the phase out of leaded motor vehicle gasoline. When sampling from the O horizon (often at 0-2 cm), Evans et al. (2005) observed Pb concentrations ranging from 60 to 200 mg/kg in Vermont, Maine, and Quebec, with lower concentrations in Quebec than in southern Vermont in 1979, but in 1996 concentrations had decreased to between 32 and 66 mg/kg with no spatial trend. Johnson and Richter (2010) also observed a substantial decrease in O-horizon (depth not specified) Pb concentrations in soil between 1978 and 2004 in West Virginia, Maryland, Pennsylvania, New Jersey, New York, and Connecticut, with a median change of -65%. However, elevation also appears to be an important factor in determining whether appreciable decreases in Pb concentration have occurred since the phase out of leaded gasoline (Kaste et al., 2006). At sites above 800 meters in the northeastern U.S., O-horizon concentrations (depths not specified) ranged from 11 to 29 kg Pb/ha, and little change in Pb concentration was observed between 1980 and 2000. In contrast, concentrations ranged from 10 to 20 kg Pb/ha at low elevation sites and decreased to 2 to 10 kg Pb/ha by 2000. This difference was likely due to greater organic turnover increasing Pb mobility at the lower elevations (Kaste et al., 2006).

Soil Pb variability depends on the strength and prevalence of nearby sources. Joshi et al. (2009) observed Pb dust concentrations to be highest at industrial sites (260 mg/kg) followed by commercial sites (120 mg/kg) and residential sites (60 mg/kg) in Singapore. Griffith et al. (2002) investigated spatial autocorrelation of soil Pb concentration at three sites: urban Syracuse, NY (0-10 cm), rural Geul River, The Netherlands (0-5 cm), and an

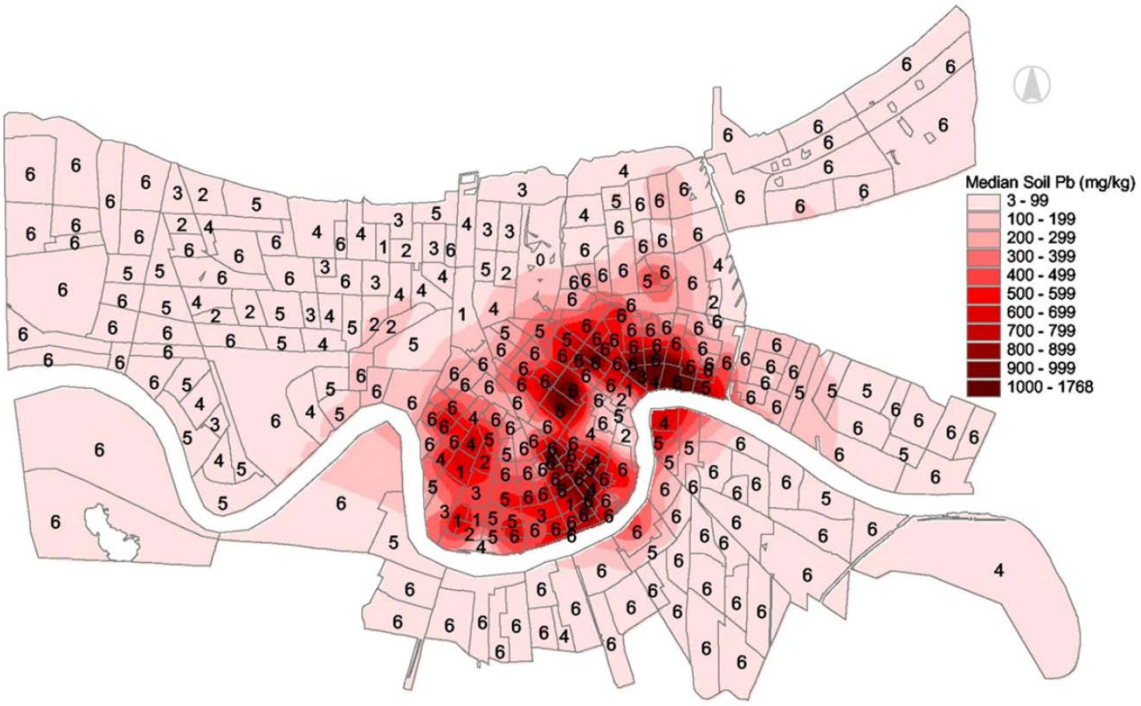
abandoned Pb Superfund site in Murray, UT (0-5 cm). In both Syracuse and Geul River, the soil Pb concentrations were not strongly correlated in space, with the exception of soil obtained near roads, which exhibited less variability. The smelting and shooting areas of the Superfund site were both demonstrated to have spatial clusters that were well correlated. Later work on the spatial distribution of metals in Syracuse (sampling depth not specified) produced similar results for that city (Griffith et al., 2009). These studies did not adjust for age of housing, although Griffith et al. (2009) did find that housing age and Pb co-vary. An association between housing age and soil Pb would likely be enhanced by such co-variation.

Emissions trends have shown that industrial activities are now one of the largest sources of soil Pb following phase out of Pb in on-road gasoline. Pruvot et al. (2006) compared urban and agricultural soils at depths of 0-25 cm near a closed Pb smelter with soils in similar environments not exposed to smelter emissions in northern France. For samples near the smelter, Pruvot et al. (2006) observed that median soil Pb levels in lawns were roughly 2 times higher, while kitchen garden soil Pb concentrations were 10 times higher and agricultural soil Pb was almost 15 times higher than soil not exposed to smelter emissions. Bonnard and McKone (2009) reported surface soil Pb concentrations at depths of 0-20 cm of 66-493 mg/kg outside homes of children living within 1 km of a Pb smelter in France; air Pb levels reported by Bonnard and McKone (2009) for this town ranged from 0.025-0.20 µg/m^3. The air samples Pingitore et al. (2009) obtained near a defunct El Paso, TX smelter (described in Section 3.5.4) found that the air Pb-TSP concentrations could largely be attributed to Pb-humate, which is created by sorption of Pb onto humic substances in soil and can be resuspended. Spalinger et al. (2007) compared soil Pb samples at depths of 0-2.5 cm from surrounding towns with those from the Bunker Hill Superfund remediation site in Idaho. Median background soil-Pb concentration was 48 mg/kg, while the median soil-Pb concentration at Bunker Hill was 245 mg/kg.

Recent studies of brownfield soils have shown variable Pb concentrations. Van Herwijnen et al. (2007) measured soils at depths of 0-2 cm near a defunct Zn smelter in Avonmouth, U.K. in areas termed low and high contamination by the authors. Total soil Pb concentration in the low contamination area was 315 mg/kg, while soil Pb concentration in the high contamination area was 1,688 mg/kg. Deng and Jennings (2006) tested various Pb extraction methods on soils obtained from over 50 brownfield sites in the greater Cleveland, OH area at depths of 0-5 cm. Comparison of twelve extraction methods for three samples produced a range of 1,780-2,636 mg/kg for one sample, 283-491 mg/kg for a second sample, and 273-499 mg/kg for a third sample. Verstraete and Van Meirvenne (2008) measured Pb in soils at a remediated brownfield site at depths of 0-5 meters in Belgium and reported average Pb concentrations to be 188 mg/kg and 224 mg/kg in two sampling campaigns. Dermont et al. (2010) fractionated soil sampled at

depths of 0-150 cm by particle size class and measured the Pb concentration in each. Pb concentrations by size bin were as follows: 125-250 µm: 1,132 mg/kg; 63-125 µm: 1,786 mg/kg; 38-63 µm: 1,712 mg/kg; 20-38 µm: 2,465 mg/kg; 0-20 µm: 3,596 mg/kg. Hence, the highest concentration was in the smallest soil particle fraction. Bulk Pb concentration over 0-250 µm particle sizes was 2,168 mg/kg.

Several studies explore the relationship between soil Pb concentration and land use. Laidlaw and Filippelli (2008) displayed data for Indianapolis, IN showing the Pb concentration at the soil surface (depths not specified) had a smoothed "bull's eye" pattern. Cities generally have a similar pattern consisting of larger quantities of Pb accumulated within the inner city and smaller quantities of Pb in outer cities (i.e., near the outskirts or suburban areas) (Filippelli and Laidlaw, 2010). Similarly, Filippelli et al. (2005) reported surface (depths not specified) soil Pb concentration distribution to have a maximum at the center of Indianapolis, IN, around the location where two interstate highways intersect, and to decrease with distance away from the center. However, the spatial distribution of Pb was presumed to reflect contributions from historic sources of on-road gasoline (Section 3.2.2.6) and Pb paint (Section 3.2.2.7). In this paper, soil Pb concentrations were also shown to decrease with distance from roadways, but the levels were roughly four times higher in urban areas compared with suburban areas. This is also illustrated for urban scale Pb accumulation in New Orleans, LA in Figure 3-26. Brown et al. (2008) also measured soil Pb concentration along three transects of Lubbock, TX at depths of 0-2 cm and observed that soil Pb decreased with increasing distance from the city center, which was the oldest part of the city.



Note: At the urban scale, Pb quantities are largest within the inner-city residential communities that surround the Central Business District where pavement and concrete cover the soil. Note the several orders of magnitude difference between the interior and the exterior areas of the city. Note that the number on each census tract indicates the number of blood Pb samples taken from that tract during the six years from which the study data were obtained.

Figure 3-26 Map of median Pb content in soil in New Orleans.

Mielke et al. (2008) compared soil Pb concentrations at depths of 0-2.5 cm for public and private housing at the center and outer sections of New Orleans and found that median and maximum soil Pb concentrations were substantially higher in the city center compared with the outer portions of the city. This study also found that private residences had higher soil Pb compared with public housing. In a separate study to examine surface soil Pb loading and concentration on 25 properties at depths of 0-2.5 cm in 25 New Orleans properties that were previously identified as having median soil Pb concentrations of at least 1,000 mg/kg, Mielke et al. (2007b) reported median and maxima soil loading rates of roughly 25,000 and 265,000 µg/m^2, respectively. Median and maxima surface soil Pb concentrations were observed to be 1,000 and 20,000 mg/kg, respectively. Clark et al. (2006) performed isotopic analysis on urban garden soils at depths of 0-10 cm and 30-40 cm in an area of Boston, MA with no large industrial sources of Pb and estimated that 40-80% of the soil Pb could be attributed to Pb-based paint while the remainder was attributed to historic Pb on-road gasoline emissions. Additional discussion of historic sources of Pb is provided in Section 3.2.2.7. Isotope

ratios for paint and gasoline references used in the Clark et al. (2006) study were obtained from Rabinowitz (1986).

Several studies have examined the effects of roadway attributes on Pb content in roadside dust. Yesilonis et al. (2008) measured metal content in surface soil samples (0-10 cm) at selected land parcels throughout Baltimore, MD, based on a stratified random sampling design that accounted for land use factors. They compared soil metals within 100 meters buffers of roadways and outside those buffers and found that median soil Pb concentration inside the buffer was significantly higher than median soil Pb concentration outside the buffers (outside: 38.7 kg/ha; inside: 134 kg/ha; $p < 0.0001$). In an analysis of the relationship between land use parameters and Pb concentration in soil in Los Angeles, CA, Wu et al. (2010) observed that soil Pb concentration at depths of 0-2.5 cm was higher near freeways and major traffic arteries compared with other locations. The (square-root transformed) age of the building on a sampled land parcel, length of highway within a 1,000-meter buffer, and length of local road within a 20-meter buffer in which the sample was obtained were significant predictors of Pb. Home age within 30 meters of a soil sample and road length within 3,000 meters of a road sample were also shown to be significant predictors of soil Pb concentration in areas not designated to be near a freeway or major traffic artery. Wu et al. (2010) concluded that both historical traffic and leaded paint contributed to Pb contamination in soils. However, Wu et al. (2010) acknowledged uncertainty in historical roadway and traffic count data, which introduces uncertainty into that conclusion. Study areas were classified as residential, commercial, park, and industrial (not specific to Pb emissions), although the authors were not able to distinguish the relative effects of each area on Pb content in roadside dust. Wu et al. (2010) reported that the highest median measured concentrations of Pb content in roadside dust were in residential freeway samples (112 mg/kg), followed by residential arterial samples (98 mg/kg), and industrial freeway samples (90 mg/kg). Additional sources of Pb to soil near roadways, such as traces of Pb in unleaded gasoline and Pb-containing wheel weights (described in Section 3.2.2.6) were not considered in this study. Amato et al. (2009) observed that deposited PM onto roadways, measured as dust samples, in Barcelona, Spain was differentially enriched with Pb compared with dust collected at a harbor area. Pb concentration in PM_{10} was highest at ring roads (229 mg/kg) and in the city center (225 mg/kg), followed by demolition and construction sites (177 mg/kg) and near a harbor (100 mg/kg). Roadside dust Pb concentration was also found to vary with roadway activity by Preciado and Li (2006); average Pb dust concentrations at a busy road were 90 mg/kg, compared with 56 mg/kg at a less busy road. Preciado and Li (2006) also examined soil Pb depth to ascertain availability of soil Pb for exposure. They observed peak soil Pb concentrations of 250-800 mg/kg at depths of 0.12-0.23 meters, depending on the soil measurement location and roadway traffic.

This finding may suggest that over time, historic emissions of Pb deposited to soil are being covered by fresh soil and hence moving further down within the soil horizons.

Size distributions of Pb-containing dust settled on the ground contain larger particles than the size distribution of ambient air Pb, described in Section 3.5.3. Preciado and Li (2006) measured the size distribution of Pb-containing dust near the roadside, as seen in Figure 3-27. For the busy highway, the mass median dust diameter estimated from the figure ranged from 34- 42 μm, depending on distance from the road. For the lower traffic highway, the mass median dust diameter estimated from the figure ranged from 64-99 μm.

Figure 3-27 Size distribution of Pb-containing dust collected near busy (HWY 1) and low traffic (HWY 17) highways.

Two recent studies focused on Pb from paint degradation by examining Pb dust loading to hard surfaces located along transects of each of the five boroughs of New York City (Caravanos et al., 2006a; Weiss et al., 2006). Caravanos et al. (2006a) used GIS to examined Pb dust loadings on top of pedestrian traffic signals and observed "hot spots," defined by the authors as at least twice the Pb dust loading at adjacent samples near major elevated bridges in upper Manhattan, the Bronx, and Queens. In Brooklyn and Staten Island, areas with high dust loading were not clearly attributed to a source. "Low spots," defined by the authors as at least two times lower Pb dust loading compared with

adjacent samples were observed in lower Manhattan, were thought to correspond with intensive cleaning efforts that followed the September 11, 2001 World Trade Center attack. Weiss et al. (2006) studied Pb concentrations of grit (granules of mixed composition found to accumulate alongside street curbs) along the transects and found that median Pb concentrations in grit under the elevated steel structures were 2.5-11.5 times higher than those obtained away from steel structures; 90th percentile values were up to 30 times higher near steel structures compared with those further from these structures.

Outdoor Pb dust has been also associated with demolition activities. Farfel et al. (2005, 2003) measured Pb dust within 100 meters of a demolition site before, immediately after, and 1 month following the demolition. They found that the rate of Pb dust fall increased by a factor of more than 40 during demolition (Farfel et al., 2003). Immediately after demolition, one demolition site had dust loadings increase by a factor of 200% for streets (87,000 µg/m^2), 138% for alleys (65,000 µg/m^2), and 26% for sidewalks (23,000 µg/m^2) compared with pre-demolition Pb dust levels. One month following demolition, Pb dust levels dropped by a factor of 45% for the street (48,000 µg/m^2), compared with post-demolition concentrations, 67% for alleys (21,000 µg/m^2), and 41% for sidewalks (14,000 µg/m^2). At another demolition site, smaller increases were observed: 29% for streets (29,000 µg/m^2), 18% for alleys (19,000 µg/m^2) and 18% for sidewalks (22,000 µg/m^2). No values were reported for the 1-month follow-up for the second site (Farfel et al., 2005).

Pb can be elevated in soils located where ammunition is used for military or hunting purposes. In a study of Pb content in sand used to cover a firing range, Lewis et al. (2010) found that 93% of bullet mass was recovered in the top 0.3 meters of the sand, and 6.4% was recovered at a depth of 0.3-0.45 meter. Pb oxides were observed to be the dominant species in the contaminated sand. Berthelot et al. (2008) studied soil Pb concentrations in grounds (0-15 cm) used for testing military tanks and munitions and measured soil Pb levels to range from 250 to 2,000 mg/kg dry basis.

3.6.2 Sediments

The recently completed Western Airborne Contaminants Assessment Project (WACAP) is the most comprehensive database, to date, on contaminant transport and depositional effects on sensitive ecosystems in the U.S. (Landers et al., 2010). The transport, fate, and ecological impacts of semi-volatile compounds and metals from atmospheric sources were assessed on ecosystem components collected from 2002-2007 in watersheds of eight core national parks (Landers et al., 2008). The goals of the study were to assess

where these contaminants were accumulating in remote ecosystems in the western U.S., identify ecological receptors for the pollutants, and to determine the source of the air masses most likely to have transported the contaminants to the parks. Pb was measured in sediments, as well as snow, water, lichen, fish, and moose during the multiyear project, and although Pb was not measured in air as a part of this study, routine monitoring find particle Pb was monitored at IMPROVE sites in the majority of national parks included in the study.

Pb concentrations in sediments from all lakes in which Pb was measured in the conterminous 48 states exhibited higher Pb concentrations near the surface relative to pre-industrial Pb levels measured at greater depth. This was not the case for other metals measured, except for cadmium (Cd) and mercury (Hg). Sediments in most lakes exhibited maximum concentrations between 1960 and 1980, followed by a decrease, as shown in Figure 3-28. A clear decline in Pb concentrations in sediments after the discontinued use of leaded on-road gasoline was observed at almost all WACAP locations, of nearly all WACAP sites in the western U.S. Sediment Pb concentrations averaged over the year in which they were obtained correlated moderately well with annual average Pb-TSP concentrations from the AQS with R = 0.63 for 1980-2004, in which WACAP data were available (NPS, 2011). Pb concentrations in sediments were much lower in Alaska, and no such decline was observed. Pb in sediments was mainly attributed to on-road gasoline use, but for some lakes a strong influence from other local sources of Pb to lake sediments was shown to be important, including Pb mining, smelting, logging, and other industrial activities. The reduction in sediment Pb concentrations shown in Figure 3-28 for recent years coincides with declines in air Pb concentrations following the phase-out of Pb anti-knock agents in gasoline and reductions of air Pb emissions from industrial activities. Elevated Pb deposition at the Glacier, Rocky Mountain, and Sequoia and Kings Canyon National Park and Preserve sites was thought by Landers et al. (2008) to reflect regional scale bioaccumulation of airborne contaminants in remote ecosystems in the western U.S. Accumulation of contaminants was shown to vary geographically; Landers et al. (2008) lists potentially influential factors causing variation in Pb deposition including proximity to individual sources or source areas, primarily agriculture, mining, and smelting operations. This finding was counter to the original working hypothesis that most of the contaminants found in western parks would originate from eastern Europe and Asia.

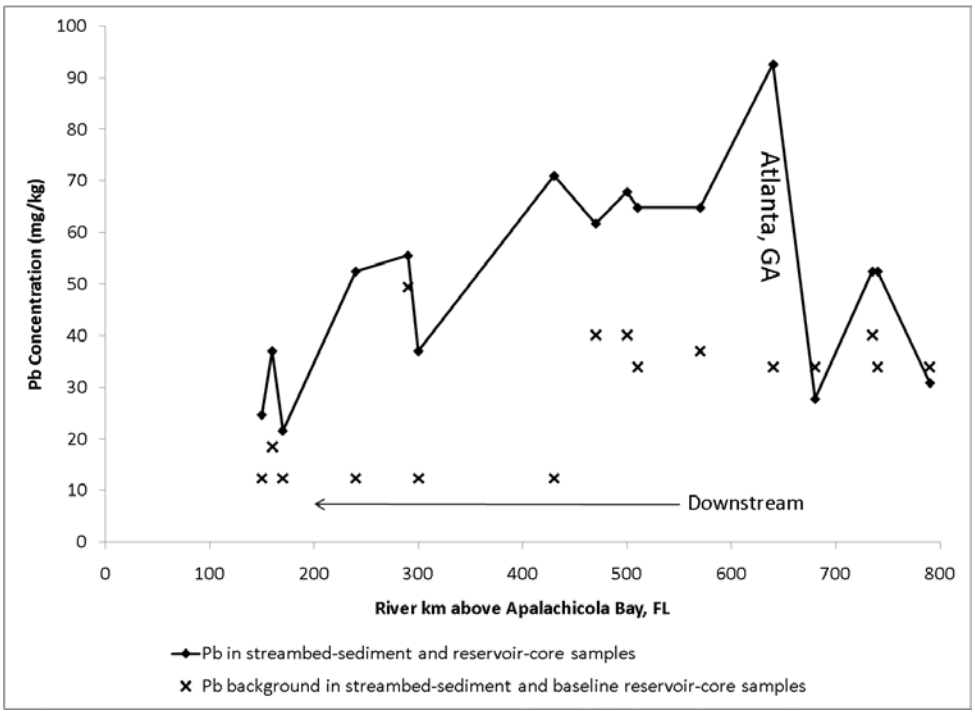
Figure 3-28 WACAP data for Pb concentration in sediment at eight National Parks and/or Preserves.

In a survey of 35 reservoirs and lakes in 16 continental U.S. states, Van Metre et al. (2006) collected data from sediment cores extending back as far as the early 1800s, and up to 2001. For most locations, they were able to match at least three bodies of water in rural (designated as 'reference'), light urban, and dense urban settings. In reference bodies of water, the median sediment Pb concentration corresponding to the 1990s was 48 mg/kg dry basis. It was 56 mg/kg dry basis in sediments from light urban bodies, and 214 mg/kg dry basis in dense urban ones (Mahler et al., 2006). Using the most distant past sediment records, Mahler et al. (2006) provided approximations of concentrations attributable to anthropogenic inputs. The median of these values for the 1990s were 28, 22, and 194 mg/kg dry basis in the reference, light urban, and dense urban bodies of water, respectively. When examining sediment cores in Lake St. Croix, MN for Pb

trends, Balogh et al. (2010) observed that the mean Pb concentration peaked in the 1970s then declined, with levels from the 1990s below 1930s levels.

Data from select regions of the U.S. illustrate that Pb concentrations in surface waters and sediment are likely to be higher in urbanized areas compared with rural locations. Figure 3-29 illustrates such variability within a single watershed for the Apalachicola, Chattahoochee, and Flint River Basin, which runs south from north of the greater Atlanta, GA metropolitan area and drains into the Gulf of Mexico at the Apalachicola Bay in the Florida panhandle. Sediment concentrations peaked near the Atlanta area and diminished as distance from the Apalachicola Bay decreased. This observation suggests that rural areas have lower Pb sediment levels compared with urban areas. Consistent with the WACAP trends shown in Figure 3-28, the data also illustrated that Pb concentrations in sediment have declined in the U.S. since 1975 (Figure 3-30). Note that Figure 3-30 does not include data near Atlanta, so the urban peak cannot be seen here as in Figure 3-29.



Note: The background refers to concentrations from undeveloped geographic regions and baseline samples are obtained from the bottom of the sediment core to minimize anthropogenic effects on the sample. Pb concentrations reported on a dry basis.

Many recent studies have illustrated the effects of natural disasters on Pb concentrations in surface water and sediment in the wake of Hurricane Katrina, which made landfall on August 29, 2005 in New Orleans, LA, and Hurricane Rita, which made landfall west of New Orleans on September 23, 2005. Pardue et al. (2005) sampled floodwaters on September 3 and September 7, 2005 following the hurricanes and observed that elevated concentrations of Pb along with other trace elements and contaminants were not irregular for stormwater but were important because human exposure to the stormwater was more substantial for Hurricane Katrina than for a typical storm. Floodwater samples obtained throughout the city on September 18, 2005 and analyzed for Pb by Presley et al. (2006) were below the limit of detection (0.04 µg/mL). Likewise, Hou et al. (2006) measured trace metal concentration in the water column of Lake Pontchartrain and at various locations within New Orleans during the period September 19 through October 9, 2005 and found that almost all Pb concentrations were below the limit of detection

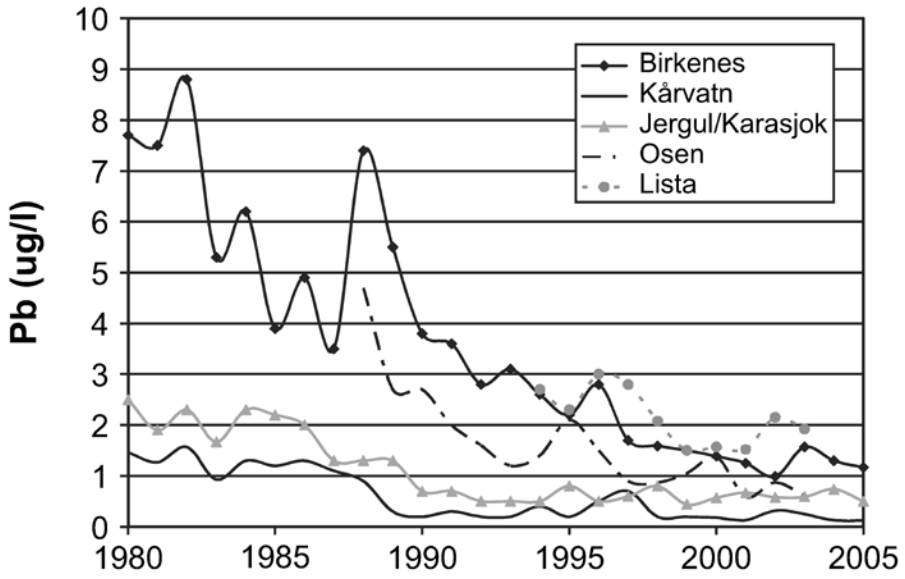
(0.0020 mg/kg). However, several studies noted no appreciable increase in Pb concentration within Lake Pontchartrain soils and sediments (Abel et al., 2010; Abel et al., 2007; Schwab et al., 2007; Cobb et al., 2006; Presley et al., 2006). Shi et al. (2010) analyzed Lake Pontchartrain sediment samples using a factored approach and found that most Pb was sequestered in carbonate-rich, iron oxide-rich, and magnesium oxide-rich sediments in which it can be more readily mobilized and potentially more bioaccessible. Zahran et al. (2010) and Presley et al. (2010) noted that soil Pb samples obtained outside schools also tended to decrease in the wake of Hurricanes Katrina and Rita, with some sites observing substantial increases and others noting dramatic reductions. These studies suggest that floodwaters can change the spatial distribution of Pb in soil and sediments to result in increased or reduced concentrations.

3.6.3 Rain

There are currently no routine measurements of Pb in precipitation in the U.S. Recent results from locations outside the U.S. were consistent with decreasing rain water concentrations described in the 2006 Pb AQCD, reflecting the elimination of Pb from on-road gasoline in most countries. From the 2006 Pb AQCD (U.S. EPA, 2006b), volume weighted Pb concentrations in precipitation collected in 1993-94 from Lake Superior, Lake Michigan and Lake Erie ranged from ~0.7 to ~1.1 µg/L (Sweet et al., 1998). These values fit well with the temporal trend reported in Watmough and Dillon (2007), who calculated annual volume-weighted Pb concentrations to be 2.12, 1.17 and 0.58 µg/L for 1989-1990, 1990-1991 and 2002-2003, respectively, in precipitation from a central Ontario, Canada, forested watershed. A similar value of 0.41 µg/L for 2002-03 for Plastic Lake, Ontario, was reported in Landre et al. (2009). For the nearby Kawagama Lake, Shotyk and Krachler (2010) gave Pb concentrations in unfiltered rainwater collected in 2008. For August and September 2008, the values were 0.45 and 0.22 µg/L, respectively, and so there had been little discernible change over the post-2000 period. In support, Pb concentrations in snow pit samples collected in 2005 and 2009 collected 45 km northeast of Kawagama Lake had not changed to any noticeable extent (0.13, 0.17, and 0.28 µg/L in 2005; 0.15 and 0.26 µg/L in 2009) (Shotyk and Krachler, 2010).

There have also been a few recently published, long-term European studies of Pb concentration in precipitation including Berg et al. (2008) and Farmer et al. (2010). Berg et al. (2008) compared the trends in Pb concentration in precipitation at Norwegian background sites in relation to the decreasing European emissions of Pb over the period 1980-2005. The Birkenes site at the southern tip of Norway is most affected by long-range transport of Pb from mainland Europe but there had been a 97% reduction in the concentration of Pb in precipitation over the 26-year time period. This was similar to the

reductions of 95% and 92% found for the more northerly sites, Karvatn and Jergul/Karasjok, respectively (Figure 3-31). A decline of ~95% in Pb concentrations in moss (often used as a biomonitor of Pb pollution) from the southernmost part of Norway, collected every 5 years over the period 1977-2005, agreed well with the Birkenes precipitation results (Berg et al., 2008). The reductions in Pb concentration in both precipitation and moss appear to agree well with the reductions in emissions in Europe (~85%) and Norway (~99%). Similar to the situation in the U.S., the greatest reductions occurred prior to the late 1990s, and relatively minor reductions have occurred thereafter; see Figure 3-31.



Source: Reprinted with permission of Pergamon Press, Berg et al. (2008)

Figure 3-31 Trends in Pb concentration in precipitation from various sites in Norway over the period 1980-2005.

Farmer et al. (2010) showed the trends in concentration of Pb in precipitation collected in a remote part of northeastern Scotland over the period 1989-2007. The 2.6- and 3.0-fold decline in mean concentration from 4.92 µg/L (1989-1991) to 1.88 µg/L (1999) and then to 0.63 µg/L (2006-2007) is qualitatively but not quantitatively in line with the sixfold decline in annual total U.K. emissions of Pb to the atmosphere over each of these time periods. After leaded on-road gasoline was banned in the U.K. in 2000, the ratio of rainwater Pb concentrations to Pb emissions (metric tons) appears to have stabilized to a near-constant value of 0.009 µg/L per metric ton. The concentrations in precipitation reported in these studies are all at the lower end of the range reported in the

2006 Pb AQCD (U.S. EPA, 2006b), and similar to concentrations reported for those studies conducted after the removal of Pb from on-road gasoline. Overall, recent studies of wet deposition tended to confirm the conclusions of the 2006 Pb AQCD (U.S. EPA, 2006b) that wet deposition fluxes have greatly decreased since the removal of Pb from on-road gasoline.

3.6.4 Snowpack

The location of Pb deposition impacts its further environmental transport. For example, Pb deposited to some types of soil may be relatively immobile, while Pb deposited to snow is likely to undergo further transport more easily when snow melts. Deposition to snow was investigated in several studies. Measurements of Pb in snowmelt during the WACAP study, showed that median Pb concentration ranged form 20-60 ng/L, with 95th percentile values ranging from 30-130 ng/L; see Figure 3-32 (NPS, 2011). Measurements in WACAP of Hg and particulate carbon deposition onto snow were thought to reflect coal combustion, and Pb was not significantly correlated with Hg in terms of either concentration or of calculated enrichment factors normalized to Al concentrations. Shotyk and Krachler (2009) reported considerably higher concentrations at two North American sites, Johnson and Parnell, in Ontario, Canada. Mean Pb concentration for contemporary snow was 672 (Johnson, n = 6; Parnell, n = 3) ng/L. Shotyk et al. (2010) presented additional values for Pb in contemporary snow samples in Simcoe County, Ontario, and these were higher than for ground and surface waters. Luther Bog and Sifton Bog snow had mean Pb concentrations of 747 and 798 ng/L, respectively. The relatively high concentrations in snow were attributed to contamination with predominantly anthropogenic Pb, although it was noted that the extent of contamination was considerably lower than in past decades.

Seasonal patterns of heavy metal deposition to snow on Lambert Glacier basin, east Antarctica, were determined by Hur et al. (2007). The snow pit samples covered the period from austral spring 1998 to summer 2002 and Pb concentrations ranged from 1.29-9.6 pg/g with a mean value of 4.0 pg/g. This was similar to a mean value of 4.7 pg/g (1965-1986) obtained by Planchon et al. (2003) for Coats Land, northwest Antarctica. Estimated contributions to the Pb in Lambert Glacier basin snow were ~1% from rock and soil dust (based on Al concentrations) and ~4.6% from volcanoes (based on the concentrations of nss-sulfate). There was almost negligible contribution from seaspray (based on Na concentrations), and so it was suggested that a substantial part of the measured Pb concentration must originate from anthropogenic sources. Highest Pb concentrations were generally observed in spring/summer with an occasional peak in winter. This contrasts with data for the Antarctic Peninsula, where highest concentrations

occurred during autumn/winter, and again with Coats Land, where high concentrations were observed throughout the winter. These differences were attributed to spatial changes in input mechanism of Pb aerosols arriving at different sites over Antarctica, which could be due to their different source areas and transport pathways. Hur et al. (2007), however, suggested that the good correlation between Pb and crustal metals in snow samples shows that Pb pollutants and crustal PM are transported and deposited in Lambert Glacier basin snow in a similar manner.

Figure 3-32 Box plots illustrating Pb concentration in snow melt at nine National Parks and Preserves.

Lee et al. (2008b) collected 42 snow samples during the period autumn 2004-summer 2005 from a 2.1-meter snow pit at a high-altitude site on the northeast slope of Mount

Everest, Himalayas. Pb concentrations ranged from 5-530 pg/g with a mean value of 77 pg/g. The mean value is clearly higher than the Hur et al. (2007) value for Antarctica but is substantially lower than a mean concentration of 573 pg/g for snow from Mont Blanc, France [1990-1991; Lee et al. (2008b)]. The mean Pb concentration for Mount Everest snow was lower during the monsoon (28 pg/g) compared with the non-monsoon periods (137 pg/g). From calculated enrichment factors (Pb/Al_{snow}:Pb/Al_{crust}), anthropogenic inputs of Pb were partly important but soil and rock dust also contributed. The low Pb concentrations during monsoon periods are thought to be attributable to low levels of atmospheric loadings of crustal dusts. Lee et al. (2008b) noted that their conclusions differ from those in Kang et al. (2007), who stated that anthropogenic contributions of Pb to Mount Everest snow were negligible because the Everest concentrations were similar to those in Antarctica. Kang et al. (2007) did not take account of the difference in accumulation rates at the two sites and had also used Pb concentrations for Antarctic snow from a study by Ikegawa et al. (1999). Lee et al. (2008b) suggested that these Pb concentrations were much higher than expected and that their snow samples may have suffered from contamination during sampling and analysis.

3.6.5 Natural Waters

Monitoring data for streams, rivers, and lakes are summarized in periodic national assessments of surface waters that are carried out periodically by EPA, and they include measurement of major biological and chemical stressors. Human exposure to Pb in drinking water is described in Section 4.1.3.3. Pb concentrations in natural waters also may reflect deposition of Pb even in remote locations. WACAP data at five National Parks and Preserves show median Pb concentrations in surface waters to range from 6 to 75 ng/L (NPS, 2011); see Figure 3-33. Four sites (Denali, Mt. Ranier, Glacier, and Olympic National Parks) were in the lower range of 6 to 20 ng/L. One site (Noatak) reported a single value of 75 ng/L. With the exception of the Noatak site, the WACAP values were in line with measurements by Shotyk and Krachler (2007) of Pb concentrations in six artesian flows in Simcoe County, near Elmvale, Ontario, Canada. The values ranged from 0.9 to 18 ng/L with a median (n = 18) of 5.1 ng/L. These are comparable with reports of a range of 0.3-8 ng/L for Lake Superior water samples (Field and Sherrell, 2003). Shotyk and Krachler (2007) also commented that such low concentrations for ground and surface waters are not significantly different from those (5.1 ± 1.4 ng/L) reported for Arctic ice from Devon Island, Canada, dating from 4,000-6,000 years ago. In a separate study, Shotyk and Krachler (2009) reported concentrations of Pb in groundwater (from two locations, Johnson and Parnell), surface water (Kawagama Lake [Ontario, Canada]) and contemporary snow (Johnson and

Parnell, as described in Section 3.6.4). The lowest mean dissolved Pb concentrations were found for groundwater: 5.9 (Johnson, n = 11) and 3.4 (Parnell, n = 12) ng/L. For lake water the mean Pb concentration was 57 (Kawagama Lake, n = 12) ng/L. The extremely low concentrations of Pb in the groundwaters were attributed to natural removal processes. Specifically, at the sampling location in Canada, there is an abundance of clay minerals with high surface area and high cation exchange capacity and these, combined with the elevated pH values (pH=8.0) resulting from flow through a terrain rich in limestone and dolostone, provide optimal circumstances for the removal of trace elements such as Pb from groundwater. Although such removal mechanisms have not been demonstrated, the vast difference between Pb concentration in snow and that in the groundwaters, indicate that the removal process is very effective. Shotyk and Krachler (2010) speculate that even at these very low Pb concentrations, much if not most of the Pb is likely to be colloidal, as suggested by the 2006 Pb AQCD (U.S. EPA, 2006b). Finally, Shotyk et al. (2010) suggest that the pristine groundwaters from Simcoe County, Canada, provide a useful reference level against which other water samples can be compared.

Figure 3-33 Boxplots of Pb concentration in surface waters measured at five National Parks and Preserves.

Although Pb concentrations in Kawagama Lake (Ontario, Canada) water were approaching "natural values," the $^{206}Pb/^{207}Pb$ ratios for the samples that had the lowest dissolved Pb concentrations of 10, 10 and 6 ng/L were 1.16, 1.15 and 1.16, respectively. These values are inconsistent with those expected for natural Pb (the clay fraction from the lake sediments dating from the pre-industrial period had values of 1.19-1.21) and it was concluded that most of the dissolved Pb in the lake water was of industrial origin. Shotyk and Krachler (2010) found that the full range of isotope ratios for Kawagama Lake water samples (Ontario, Canada) was 1.09 to 1.15; this was not only much lower than the stream water values entering the lake but also lower than the values attributed to leaded on-road gasoline in Canada (~1.15). The streamwater ratio values were ~1.16 to 1.17, while those for rainwater were as low as 1.09; in good agreement with the lower

lake water values. This means that there must be an additional atmospheric source of Pb, which has a lower $^{206}Pb/^{207}Pb$ ratio than leaded on-road gasoline. Supporting evidence came from contemporary samples such as near surface peat, rainwater and snow, all of which confirmed a trend away from natural Pb (1.191 to 1.201) to lower $^{206}Pb/^{207}Pb$ ratios. The local smelting activities (Sudbury) were unlikely to be the source of anthropogenic Pb as Sudbury-derived emissions exhibit a typical $^{206}Pb/^{207}Pb$ ratio of ~1.15, similar to leaded on-road gasoline. Instead, it was suggested that long-range transport of Pb from the smelter at Rouyn-Noranda (known as the "Capital of Metal," NW Quebec) may still be impacting on Kawagama Lake but no Pb isotope data was quoted to support this supposition. Several studies, summarized in Mager (2012), reported Pb concentrations in matched reference and mining-disturbed streams in Missouri and the western U.S. They are summarized in Table 3-11.

The range of Pb levels in various saltwater environments are available from several studies although the values are not specific to the U.S. A range of 0.005-0.4 µg Pb/L for seawater was reported by Leland and Kuwabara (1985) to reflect localized anthropogenic inputs in marine environments based on references from prior to 1980 and 0.01 to 27 µg Pb/L by Sadiq (1992). In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems (U.S. EPA, 2008b).

Table 3-11 Pb concentrations from stream food-webs; in mining-disturbed areas of Missouri and the western U.S.

Area	Total Pb in water (µg/L)	Dissolved Pb (µg/L)
Animas River, CO (Besser et al., 2001):		
Reference Streams	<1.8	<0.2
Mining-disturbed areas	0.9–8.6	<0.1–6.9

3.6.6 Vegetation

The 2006 Pb AQCD (U.S. EPA, 2006b) presented data on Pb in vegetation. The main conclusions were that Pb uptake was strongly affected by pH, and acidic soils are most likely to have Pb in solution for absorption by plants. Additionally, the 2006 Pb AQCD (U.S. EPA, 2006b) states that most Pb stored within vegetation is stored in roots rather than fruits or shoots. Recent measurements from the WACAP study (NPS, 2011) have shown some Pb storage in lichens. Median Pb concentrations ranged from 0.3 mg/kg in Noatak National Park (Alaska) to 5 mg/kg in Glacier National Park (Montana), with substantial variation in the Glacier and Olympic National Park (Washington State) samples; Figure 3-34. Landers et al. (2008) state that lichen Pb concentrations have decreased substantially from the 1980s and that metal concentrations were within background levels for these remote Western sites.

Mosses can be used effectively for monitoring trends in Pb deposition as demonstrated in many studies (Harmens et al., 2010; Harmens et al., 2008). For example, Harmens et al. (2008) showed that a 52% decrease in deposited Pb concentrations corresponded to a 57% decrease in Pb concentrations in moss. Farmer et al. (2010) showed that there was good agreement between the $^{206}Pb/^{207}Pb$ ratio for precipitation and mosses collected in northeast Scotland. A study in the Vosges Mountains (France) also found a ratio value of 1.158 for a moss sample and a surface soil litter value of 1.167 and concluded that 1.158 to 1.167 represented the current atmospheric baseline (Geagea et al., 2008). For rural northeast Scotland, a combination of sources is giving rise to a $^{206}Pb/^{207}Pb$ ratio of ~1.15 in recent precipitation and mosses (Farmer et al., 2010). Clearly, sources with a lower ratio than coal (~1.20) must be contributing substantially to the overall emissions. Pb

from waste incineration has been implicated as a possible current source (cf. typical $^{206}Pb/^{207}Pb$ ratios for Pb from European incineration plants are ~1.14 to 1.15 [de la Cruz et al. (2009) and references therein].

Pb has been measured on vegetation near roads in recent years. Hasselbach et al. (2005) measured Pb and other metals in mosses to assess deposition of metals along a haul road leading from a port to the Red Dog Zn-Pb mine in Northwest Alaska. They observed that moss concentrations of Pb decreased with increasing distance from the road, while subsurface soils (average depth = 62 meters) did not vary with distance from the road. The strong moss Pb gradient and constant subsurface soil Pb concentrations imply that Pb concentrations in mosses were primarily attributed to deposition and did not have appreciable contributions from soil. Throughout the study area, median moss Pb concentration was 16.2 mg/kg (dry basis), with a range of 1.1-912.5 mg/kg. Concentrations along the port road also diminished with increasing distance from the port, where ore loading operations take place. Hasselbach et al. (2005) attributed the concentrations to ore dust generated during loading operations at the port and mine along with fugitive dust escaping during truck transport. Maher et al. (2008) measured average Pb loading onto tree leaves near highways to be 29 $\mu g/m^2$ (max: 81 $\mu g/m^2$) at elevations ranging from 0.30 to 2.1 meters.

Trends in Pb concentration among flora have decreased in recent years. For example, Franzaring et al. (2010) evaluated data from a 20-year biological monitoring study of Pb concentration in permanent forest and grassland plots in Baden-Württemberg, southwest Germany. Grassland and tree foliage samples were collected from 1985-2006. The samples were not washed and so atmospheric deposition rather than uptake from the soil probably predominates. For all foliage (beech and spruce), Pb concentrations have shown large reductions over time, particularly in the early 1990s. The Pb concentrations in the grassland vegetation also decreased from the late 1980s to the early 1990s but the trend thereafter was found to be statistically non-significant. The reduction corresponded to the phase-out of leaded on-road gasoline in Germany. Similarly, Aznar et al. (2008a) observed that the decline in Pb concentrations in the outer level of tree rings corresponded with the decline in Cu smelter emissions in Gaspé Peninsula in Canada; Figure 3-35. Both Pb concentrations and Pb isotope ratios declined with distance from the smelter (Aznar et al., 2008b; Aznar et al., 2008a).

Figure 3-35 Trends in regional pollution near a copper (Cu) smelter in Canada and Pb concentrations at the boundary of heartwood trees within roughly 75 km of the smelter.

3.6.7 Aquatic Bivalves

Data from invertebrate waterborne populations can serve as in indicator of Pb contamination because animals such as mussels and oysters take in contaminants during filter feeding. Kimbrough et al. (2008) surveyed Pb concentrations in mussels, zebra mussels, and oysters along the coastlines of the continental U.S. In general, they observed the highest concentrations of Pb in the vicinity of urban and industrial areas. Company et al. (2008) measured Pb concentrations and Pb isotope ratios in bivalves along the Guadiana River separating Spain and Portugal. Analysis of Pb isotope ratio data suggested that high Pb concentrations were related to historical mining activities in the

region. Elevated Pb concentrations were also observed by Company et al. (2008) in the vicinity of more populated areas. Couture et al. (2010) report data from a survey of the isotopic ratios of Pb in *Mytilus edulis* blue mussel, collected off the coast of France from 1985-2005. The results indicated that the likely source of Pb in mussel tissue is from resuspension of contaminated sediments enriched with Pb runoff from wastewater treatment plants, municipal waste incinerators, smelters and refineries rather than from atmospheric deposition (Couture et al., 2010).

3.6.8 Vertebrate Populations

Pb concentrations in fish fillet and liver were measured through the WACAP study in eight National Parks and Preserves (NPS, 2011). For fish fillet, Pb concentrations ranged from 0.0033-0.30 mg/kg dry basis, with a median of 0.016 mg/kg dry basis. Liver stores were several times higher, with Pb concentrations ranging from 0.011-0.97 mg/kg dry basis and a median of 0.096 mg/kg dry basis. Pb concentrations in moose meat and liver were also measured at the Denali National Park and Preserve (Alaska) as part of WACAP (NPS, 2011). Moose meat Pb concentrations ranged from 0.021-0.23 mg/kg dry basis with a median of 0.037 mg/kg dry basis. Pb concentrations in moose liver ranged from 0.025-0.11 mg/kg dry basis with a median of 0.053 mg/kg dry basis. Boxplots of measured Pb concentrations in fish fillet and liver are shown in Figure 3-36, and boxplots of measured Pb concentrations for moose meat and liver are shown in Figure 3-37. For fish and meat tissues, median and maximum Pb concentrations were substantially lower than values reported in the 2006 Pb AQCD (U.S. EPA, 2006b). Similarly, in a study of Pb levels in moose teeth from Isle Royale, MI, (Vucetich et al., 2009) median and mean Pb levels underwent a statistically significant decrease from the period 1952-1982 to 1983-2002 in both calves and adult moose. For 1952-1982, Pb concentrations were relatively constant, and a linear decline ($R^2 = 0.86$) was observed for 1983-2002. These findings suggest an overall decline but still some Pb accumulation in fish and moose in these remote locations occurring recently.

3.7 Summary and Conclusions

3.7.1 Sources of Atmospheric Pb

The 2006 Pb AQCD (U.S. EPA, 2006b) documented the decline in ambient air Pb emissions following the ban on alkyl-Pb additives for on-road gasoline. Pb emissions declined by 98% from 1970 to 1995 and then by an additional 76% from 1995 to 2008, at which time national Pb emissions were 964 tons/year. As was the case for the 2008 NAAQS review, piston-engine aircraft emissions currently comprise the largest share (57%) of total atmospheric Pb emissions nationally (U.S. EPA, 2011a). Other sources of ambient air Pb, in approximate order of importance with regard to national totals, include metal working and mining, fuel combustion, other industrial sources, roadway related sources, and historic Pb. Although piston-engine aircraft collectively comprise the largest emissions source, the highest emitting individual industrial sites produce more ambient air Pb emissions than individual airports.

3.7.2 Fate and Transport of Pb

The atmosphere is the main environmental transport pathway for Pb, and on a global scale atmospheric Pb is primarily associated with fine PM. Pb in fine PM is transported long distances and found in remote areas. Atmospheric Pb deposition peaked in the 1970s, followed by a decline. Both wet and dry deposition are important removal mechanisms for atmospheric Pb. Wet deposition is more important for fine Pb, and Pb associated with coarse PM is usually removed by dry deposition. Local deposition fluxes are much higher near industrial sources, and a substantial amount of emitted Pb is deposited near sources, leading to increased soil Pb concentrations. Deposition does not cause an ultimate sink for Pb because particles are potentially resuspended and redeposited many times before reaching a site where further transport is unlikely, especially for dry deposition.

In water, Pb is transported as free ions, soluble chelates, or on surfaces of iron and organic rich colloids. In most surface waters, atmospheric deposition is the largest source of Pb, but urban runoff and industrial discharge are also considerable. A substantial portion of Pb in runoff ultimately originates from atmospheric deposition, but substantial amounts of Pb from vehicle wear and building materials can also be transported by runoff waters without becoming airborne. Often the majority of Pb transport by runoff occurs at the beginning of a rainfall event. Pb is rapidly dispersed in water, and highest concentrations of Pb are observed near sources where Pb is deposited.

Transport in surface waters is largely controlled by exchange with sediments. The cycling of Pb between water and sediments is governed by chemical, biological, and mechanical processes, which are affected by many factors. Organic matter in sediments has a high capacity for accumulating trace elements like Pb. Binding of anoxic sediments to sulfides is a particularly important process that affects Pb bioavailability. Pb is relatively stable in sediments, with long residence times and limited mobility. However, Pb-containing sediment particles can be remobilized into the water column. Resuspended Pb is largely associated with OM or Fe and Mn particles. This resuspension of contaminated sediments strongly influences the lifetime of Pb in water bodies and can be a more important Pb source to the water column than atmospheric deposition. Resuspension of sediments largely occurs during discrete events related to storms.

A complex variety of factors influence Pb retention in soil, including hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, animal holes, geochemical reactions, colloid amounts, colloidal surface charge, and pH. Leaf litter can be an important temporary sink for metals from the soil around and below leaves, and decomposition of leaf litter can reintroduce substantial amounts of Pb into soil "hot spots," where re-adsorption of Pb is favored. A small fraction of Pb in soil is present as the free Pb^{2+} ion. The fraction of Pb in this form is strongly dependent on soil pH.

In summary, environmental distribution of Pb occurs mainly through the atmosphere, from where it is deposited into surface waters and soil. Pb associated with coarse PM deposits to a great extent near sources, while fine Pb-PM can be transported long distances. Surface waters act as an important reservoir, with half-lives of Pb in the water column largely controlled by rates of deposition to and resuspension from bottom sediments. Pb retention in soil depends on Pb speciation and a variety of factors intrinsic to the soil.

3.7.3 Ambient Pb Monitoring

Since the publication of the 2006 Pb AQCD for Pb (U.S. EPA, 2006b) there has been little progress in the state of the science regarding monitoring technology and monitor siting criteria for representation of population exposures to airborne Pb and Pb of atmospheric origin. Our understanding of sampling errors in the existing FRM, of possible alternatives to existing Pb-TSP sampling technology, and of particle size ranges of Pb particles occurring in different types of locations have changed little in that time. In addition to monitors used historically for sampling Pb-PM, several single stage and multi-stage impactors and inlets used for sampling PM are also potential options for

monitoring Pb particles smaller than 15 μm. Ambient air Pb deposits onto soil or dust. As described in Section 4.1, the size distribution of dust and soil Pb particles is larger than the size distribution of ambient air Pb particles. The existing samplers reasonably capture the airborne fraction of ambient Pb that is available for human exposure.

The current Pb monitoring network design requirements include two types of monitoring sites: source-oriented and non-source-oriented. Source-oriented monitoring sites are required near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. Non-source-oriented monitoring of Pb-TSP or Pb-PM_{10} is also required at NCore sites in CBSAs with a population of at least 500,000.

In addition to Pb-TSP monitoring for the purposes of judging attainment with the NAAQS, Pb is also routinely measured in smaller PM fractions in the CSN, IMPROVE, and the NATTS networks. While monitoring in multiple networks provides extensive geographic coverage, measurements between networks are not directly comparable in all cases because different PM size ranges are sampled in different networks. Depending on monitoring network, Pb is monitored in TSP, PM_{10}, or $PM_{2.5}$ using high-volume or low-volume samplers.

3.7.4 Ambient Air Pb Concentrations

Ambient air Pb concentrations have declined drastically over the period 1980-2010. The median annual maximum 3-month average concentration of Pb-TSP has dropped by 97% from 0.87 $\mu g/m^3$ in 1980 to 0.03 $\mu g/m^3$ in 2010. The decline can be attributed to the phase-out of Pb antiknock agents in on-road fuel and reductions in industrial use and processing of Pb, as described in Section 3.2.1. The mean of maximum 3-month average concentrations for source-oriented monitors was skewed toward the 75th percentile of the data distribution and exceeded the level of the NAAQS, indicating that highest ambient air Pb concentrations occur near a subset of source-oriented monitors. Studies in the peer-reviewed literature have shown slightly elevated Pb concentrations downwind of industrial sources and airports.

Spatial variability was observed in ratios and correlations of Pb within different size fractions. Urban or suburban land types did not appear to affect sampled size distributions. Studies in the peer-reviewed literature suggest that proximity to industrial sources or some roadways can affect the Pb-PM size distribution. Pb concentrations exhibit varying degrees of association with other criteria pollutant concentrations. Overall, non-source Pb-TSP was moderately associated with CO, $PM_{2.5}$, and PM_{10}, which may indicate some role of traffic in Pb exposure. Among trace metals speciated from

$PM_{2.5}$, Pb was not associated with most pollutants; Pb did associate with Zn, although that association was low-to-moderate, suggesting mobile source emissions contributing to the Pb. EC, Cu, OC, and Br concentrations also exhibited low-to-moderate associations with Pb concentrations. Such correlations may suggest some common sources affecting the pollutants. Finally, the evidence on natural background Pb suggests a plausible background airborne Pb range of 0.02 to 1 ng/m^3.

3.7.5 Ambient Pb Concentrations in Non-Air Media and Biota

Atmospheric deposition has led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with highest concentrations near Pb sources, such as metal smelters. Since the phase-out of Pb from on-road gasoline, concentrations in these media have decreased to varying degrees. In rain, snowpack, and surface waters, Pb concentrations have decreased considerably. Declining Pb concentrations in tree foliage, trunk sections, and grasses have also been observed. In contrast, Pb is retained in soils and sediments, where it provides a historical record of deposition and associated ambient concentrations. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth and indicate peak concentrations between 1960 and 1980, when leaded on-road gasoline was at peak use. Concentrations of Pb in moss, lichens, peat, and aquatic bivalves have been used to understand spatial and temporal distribution patterns of air Pb concentrations. Ingestion and water intake are the major routes of Pb exposure for aquatic organisms, and food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife. Overall, Pb concentrations have decreased substantially in media through which Pb is rapidly transported, such as air and water. Substantial Pb remains in soil and sediment sinks. In areas less affected by major local sources, the highest concentrations are below the surface layers and reflect the previous use of Pb in on-road gasoline and emissions reductions from other sources.

[a]The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 appendix R and as such cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS.

[b]Sites listed in the bottom six rows of this table fall in the upper 90th percentile of the data pooled by site.

Table 3-15 Distribution of 3-month moving average Pb-TSP concentrations (µg/m^3) nationwide, non-source-oriented monitors, 2008-2010.

Concentrations of Pb Measured using PM_{10} Monitors (for Concentrations and Trends)

Figure 3-38 displays maximum 3-month averages for Pb-PM_{10} concentrations for 36 counties in which measurements were obtained. Among the 36 counties in which PM_{10} monitoring was conducted, only one county, Gila County, AZ, reported concentrations above 0.076 µg/m^3. Three other counties reported concentrations greater than 0.016 µg/m^3: Wayne County, MI, Boyd County, KY, and the county of St. Louis City, MO.

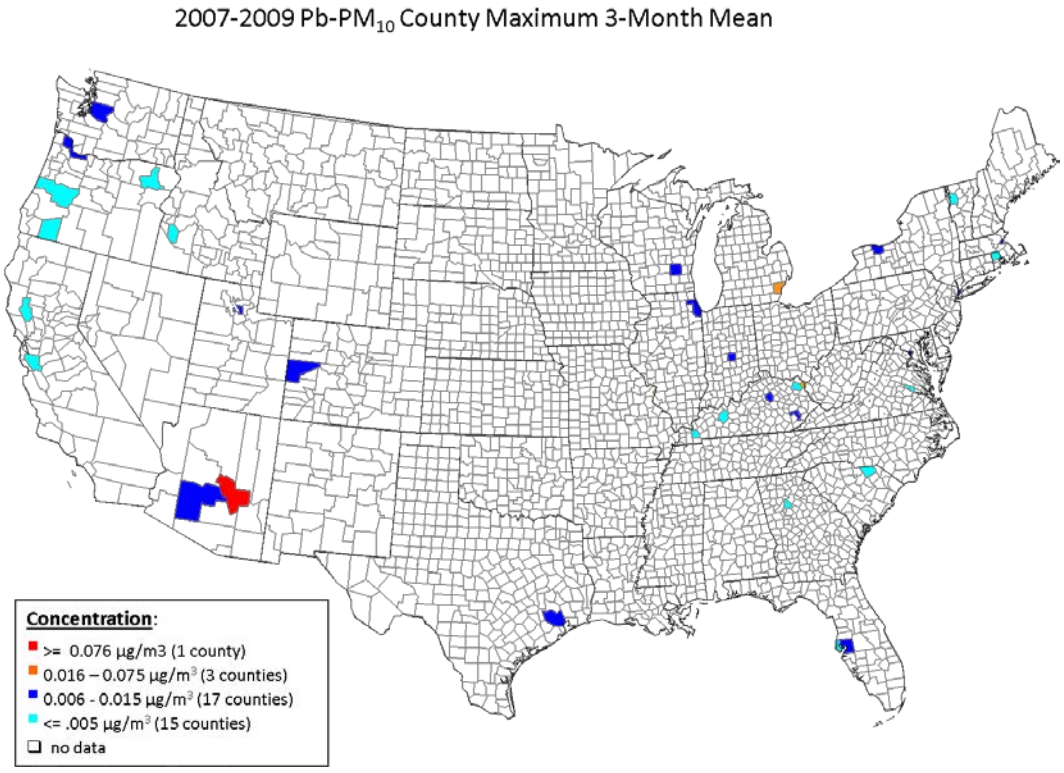

Figure 3-38 Highest county-level Pb-PM_{10} concentrations (µg/m^3), maximum 3-month average, 2007-2009.

Concentrations of Pb Measured using $PM_{2.5}$ Monitors (for Speciation Concentrations and Trends)

Figure 3-39 displays maximum 3-month average county-level data for Pb in $PM_{2.5}$ concentrations for 323 counties in which $PM_{2.5}$ measurements were obtained for speciation in the CSN and IMPROVE networks. The data presented here are not compared to the NAAQS because $PM_{2.5}$ monitors are not deployed for the purpose of evaluating compliance for the NAAQS. Among the 323 counties in which $PM_{2.5}$ monitoring was conducted, only eleven counties reported concentrations greater than 0.016 µg/m^3: Jefferson, AL, San Bernardino, CA, Imperial, CA, Wayne, MI, Jefferson, MO, Erie, NY, Lorain, OH, Allegheny, PA, Berks, PA, Davidson, TN, and El Paso, TX.

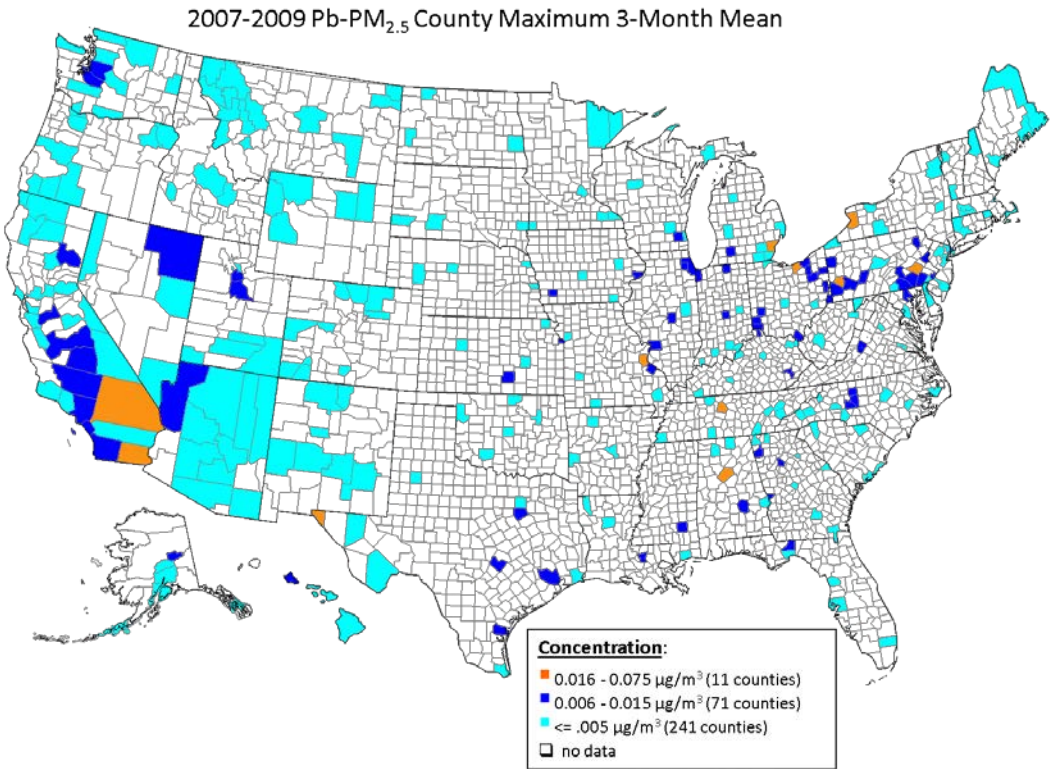

Figure 3-39 Highest county-level Pb-$PM_{2.5}$ concentrations (µg/m^3), maximum 3-month average, 2007-2009.

3.8.2 Intra-urban Variability

Intra-urban variability in Pb concentrations reported to AQS was described in detail for Los Angeles County, CA (Los Angeles), Hillsborough and Pinellas Counties, FL (Tampa), Cook County, IL (Chicago), Jefferson County, MO (Herculaneum), Cuyahoga County, OH (Cleveland), and Sullivan County, TN (Bristol) were selected for this assessment to illustrate the variability in Pb concentrations measured across different metropolitan regions with varying Pb source characteristics. Four of the counties encompass large cities (Los Angeles, Tampa, Chicago, and Cleveland). All six counties contain source-oriented monitors. Maps and wind roses (graphs representing wind direction and wind speed at a location) are presented in this Chapter 3 Appendix for each of the six urban areas. Additionally, annual and seasonal box plots of the Pb concentration distributions and intra-monitor correlation tables are presented to illustrate the level of variability throughout each urban area.

Maps of six areas (Los Angeles County, CA; Hillsborough/Pinellas Counties, FL; Cook County, IL; Jefferson County, MO; Cuyahoga County, OH; and Sullivan County, TN) are shown to illustrate the location of all Pb monitors meeting the inclusion criteria. Wind roses for each season are also provided to help put the source concentration data in context. Letters on the maps identify the individual monitor locations and correspond with the letters provided in the accompanying concentration box plots and pair-wise monitor comparison tables. The box plots for each monitor include the annual and seasonal concentration median and interquartile range with whiskers extending from the 5th to the 95th percentile. Data from 2008-2010 were used to generate the box plots, which are stratified by season as follows: 1 = winter (December-February), 2 = spring (March-May), 3 = summer (June-August), and 4 = fall (September-November). The comparison tables include the Pearson correlation coefficient (R), Spearman rank-ordered correlation coefficient (ρ), the 90th percentile of the absolute difference in concentrations (P90) in μg/m^3, the coefficient of divergence (*COD*) and the straight-line distance between monitor pairs (d) in km. The *COD* provides an indication of the variability across the monitoring sites within each county and is defined as follows:

$$COD_{jk} = \sqrt{\frac{1}{p}\sum_{i=1}^{p}\left(\frac{X_{ij} - X_{ik}}{X_{ij} + X_{ik}}\right)^2}$$

Equation 3A-1

where X_{ij} and X_{ik} represent the observed hourly concentrations for time period i at sites j and k, and p is the number of paired hourly observations. A *COD* of 0 indicates there are

no differences between concentrations at paired sites (spatial homogeneity), while a *COD* approaching 1 indicates extreme spatial heterogeneity.

In certain cases, the information contained in these figures and tables should be used with some caution since many of the reported concentrations for the years 2008-2010 are near or below the analysis method's stated method detection limit (MDL). The MDL is generally taken as 0.01 because it is the upper value of the range of MDLs reported for atomic absorption (AA) and Emissions Spectra ICAP methods, which were the two methods reported in the AQS to have been used for analysis of FRM samples (Rice, 2007). Generally, data are reported to the hundredth place, so this assumption is reasonable. The approximate percentage of data below the MDL (to the nearest 5%) is provided for each site along with box plots of seasonal Pb concentration at monitors within each urban area studied.

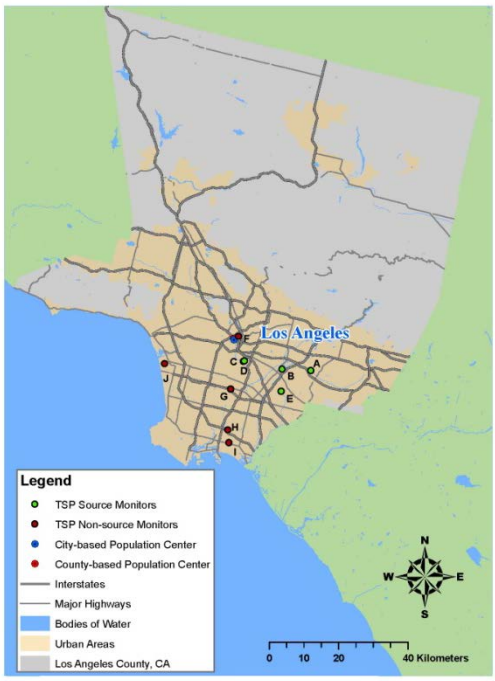
Figure 3-40 illustrates Pb monitor locations within Los Angeles County, CA. Ten monitors are located within Los Angeles County, five of which were source-oriented and the other five were non-source-oriented monitors. Monitor A was located immediately downwind of the Quemetco battery recycling facility in the City of Industry, CA. This source was estimated to produce 0.32 tons of Pb/yr (U.S. EPA, 2008c). Monitor C was sited in a street canyon just upwind of the Exide Pb recycling facility, which was estimated to produce 2.0 tons of Pb/yr (U.S. EPA, 2008c). Monitor D was situated slightly northwest of the same Pb recycling facility. It is still in relatively close proximity but not downwind on most occasions. Monitor B was located 12 km downwind of the Exide facility. Monitor E was located nearby the Trojan Battery recycling facility, which emitted 0.79 tons Pb/yr (U.S. EPA, 2008c). Location of the non-source-oriented monitors varied. Monitor F was positioned on a roof top 60 meters away from a 4-lane arterial road and 100 meters from of a railroad. Monitor G was located on a rooftop approximately 20 meters from an 8-lane arterial road, and monitor H was positioned at the curbside of a four-lane road roughly 650 meters north of that road's junction with Interstate I-405. Monitor I was sited in a parking lot roughly 80 meters from a four-lane road, and monitor J was located approximately 130 meters south of a 4-lane highway. Figure 3-41 displays seasonal wind roses for Los Angeles County. In spring, summer, and fall, the predominant winds come from the west-southwest. During winter, wind direction varies with a portion from the west-southwest and the remainder from the east. The highest winds during winter come more frequently from the west-southwest.

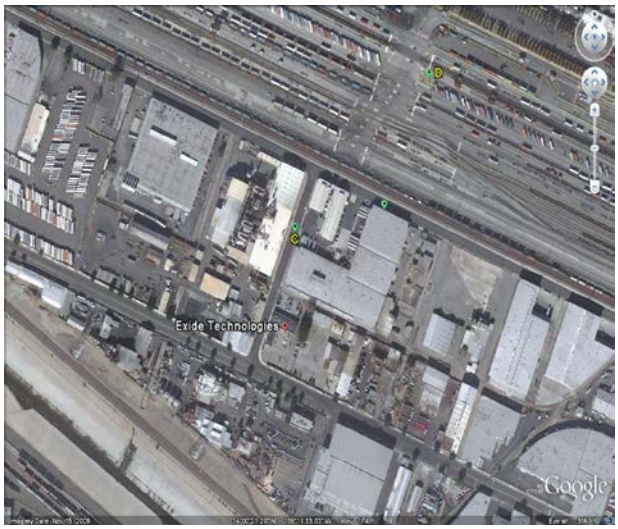
The maps shown in Figure 3-40 for source-oriented monitors A-E illustrate the different conditions captured by the monitors; this informs analysis of the seasonal and year-round concentrations reported in Figure 3-42. The average annual concentration at monitor A was 0.074 $\mu g/m^3$. The 95th percentile exceeded the level of the NAAQS in the spring

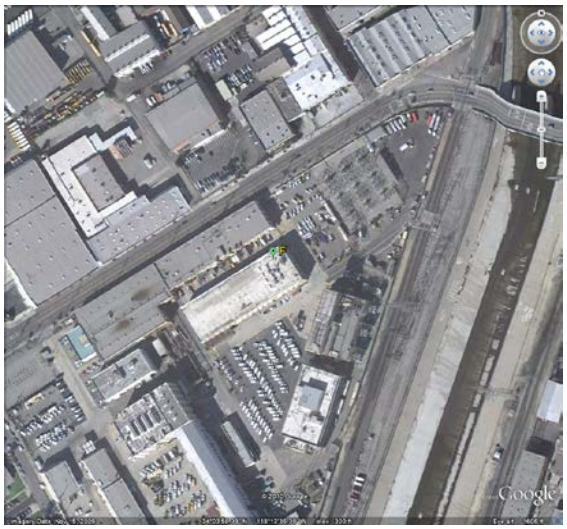
(0.16 μg/m^3) and summer (0.18 μg/m^3). Monitor C reported the highest concentrations in Los Angeles County, with a year-round mean of 0.68 μg/m^3. Given the position of this monitor with respect to the Exide facility, there is the potential for recirculation of fugitive Pb emissions in the air sampled by that monitor. The average annual Pb concentration at monitor D was 0.12 μg/m^3, and the 75th percentile of year-round data exceeded the level of the NAAQS; in spring, the 70th percentile exceeded 0.15 μg/m^3. Monitor B reported the lowest values among the source-oriented monitors with an average annual concentration of 0.013 μg/m^3. Note that 75% of reported values were below the MDL for this site, and no data from this site exceeded the level of the NAAQS. The annual average concentration at monitor E was 0.068 μg/m^3, and the 95th percentile of concentration was 0.17 μg/m^3.

The non-source-oriented monitors located at sites F-J all recorded low concentrations, with average values ranging from 0.004 to 0.018 μg/m^3 (Figure 3-42). The highest average year-round concentrations were recorded at site F. The 95th percentiles at these sites ranged from 0.01 to 0.04 μg/m^3. There is much less certainty in the data recorded at the non-source-oriented sites, because 45-95% of the data from these monitors were below the MDL. Additionally, only one of the non-source-oriented monitors (monitor H) was positioned at roadside, and none of the non-source-oriented monitors were located at the side of a major highway.

Intersampler correlations (Table 3-20), illustrate that Pb has high intra-urban spatial variability. For the source-oriented monitors, the highest correlation ($R = 0.59$, $\rho = 0.57$) occurred for monitors C and D, which covered the same site. Because monitor D was slightly farther from the Exide source and slightly upstream of the predominant wind direction, the signal it received from the source site was correspondingly lower. Hence, the correlation between these sites was moderate despite their relatively close proximity. In general, low or even negative correlations were observed between the source-oriented and non-source-oriented monitors. The exception to this was the Spearman-ranked correlation between source-oriented monitor B and non-source-oriented monitor F, with $\rho = 0.74$. Pearson correlation was much lower for this pair ($R = 0.33$). Monitors B and F are roughly 16 km apart, whereas monitor B is only 12 km from monitors D and C, 8 km from monitor E, and 6 km from monitor A. It is possible that monitors B and F both captured a source that was either longer in range or more ubiquitous and so would have been obscured by the stronger source signals at sites A, C, D, and E. Comparisons between the non-source-oriented monitors revealed moderate correlation between sites (G to J [$R = 0.29$ to 0.71, $\rho = 0.37$ to 0.65]). Sites G, H, I and J are all located in the southwestern quadrant of Los Angeles. It is possible that they are also exposed to a ubiquitous source that produces a common signal at these four sites.







Note: Monitor locations are denoted by green markers, and source locations are denoted by red markers. Top: view of all Pb FRM monitors in Los Angeles County. Bottom left: Close up of the industrial site near monitors C and D. Bottom right: Close up of the populated area captured by monitor F.

Each comparison contains (in order): Pearson rank-order correlation (R), Spearman rank-order correlation (p), the difference between the 90th and 10th percentile data (P90), and the coefficient of divergence (*COD*).

Figure 3-43 illustrates Pb monitor locations within Hillsborough and Pinellas Counties in FL, which comprise the greater Tampa-St. Petersburg metropolitan area. Two source-oriented monitors (A and B) were located within Hillsborough County, and one non-source-oriented monitor (C) was located in Pinellas County. Monitor A was located 360 meters north-northeast of the EnviroFocus Technologies battery recycling facility, which produced 1.3 tons/year (U.S. EPA, 2008d), and monitor B was located 320 meters southwest of the same facility. Monitor C was located next to a two-lane road in Pinellas Park, FL.

Figure 3-44 displays seasonal wind roses for the Tampa-St. Petersburg metropolitan area. These wind roses suggest shifting wind directions throughout the winter, spring, and summer. During the winter, the highest winds came from the north and northeast with little influence from the west and southwest. During spring and summer, easterly and westerly winds were evident from the wind rose, with winds from the west being slightly higher in wind speed. During autumn, winds came predominantly from the northeast with little signal from the west or south.

Seasonal and year-round concentrations are reported for Hillsborough and Pinellas Counties in Figure 3-45. The average annual concentration at monitor A was 0.15 $\mu g/m^3$, and the 95th percentile was 0.70 $\mu g/m^3$. During winter, the 60th percentile of the data met the level of the NAAQS. At this site, the highest concentrations occurred during summer, which corresponded to the time when westerly winds were stronger. Concentration data at monitor B were much higher, with an annual average of 0.45 $\mu g/m^3$ and a 95th percentile of 1.9 $\mu g/m^3$. Annually, the 55th percentile exceeded the level of the NAAQS, and in autumn the 45th percentile exceeded the NAAQS. The highest concentrations occurred in autumn, coinciding with the time when winds blew from the northeast, when monitor B was most often downwind of the battery recycling facility. The non-source-oriented monitor C always reported concentrations of 0.0 $\mu g/m^3$. This is likely related to its location next to a quiet road in a small city.

Intersampler correlations, shown in Table 3-21, illustrate that Pb has high intra-urban spatial variability. The source-oriented monitors were anticorrelated ($R = -0.09$, $\rho = -0.08$). This was likely related to the fact that they were designated to monitor the same source and were downwind of the source at different times.

Figure 3-46 illustrates Pb monitor locations within Cook County, IL. Eight monitors were located within Cook County, four of which were designated by the Illinois Environmental Protection Agency (IEPA) in data reported to the AQS as source-oriented and the other four were non-source-oriented monitors. Monitor A was situated within 10 km of 6 sources ranging in emissions from 0.14 to 1.08 tons/year (U.S. EPA, 2008a). Monitor A was also sited in the median of Interstate I-90/I-94. Monitor B was located on the northern roadside of Interstate I-290, 5 meters from the closest lane of traffic and was within 10 km of 2 Pb sources (0.41 and 1.08 tons/year) (U.S. EPA, 2008a). Monitor C was also located within 10 km of 6 sources in Cook County and Lake County, IN; the largest of those sources was 2.99 tons/year and was located 8 km southeast of monitor C (U.S. EPA, 2008a). Monitor C was placed on the roof of a high school. Monitor D was located roughly 60 meters west of Interstate I-294 and adjacent to O'Hare International Airport. Monitor E was located on the rooftop of a building rented for government offices in Alsip, IL, a suburb south of Chicago. This location was roughly 1 km north of Interstate I-294 but not located on an arterial road; it was 9 km southeast of a 0.56 tons/year source (U.S. EPA, 2008a). Monitor F was sited in the parking lot of a water pumping station, 100 meters north of Interstate I-90 and 300 meters northwest of the junction between Interstates I-90 and I-94. This site was 2 km north-northwest of a 0.10 tons/year source (U.S. EPA, 2008a). Monitor G was situated atop an elementary school in a residential neighborhood on the south side of Chicago, roughly 100 meters

south of a rail line and over 300 meters west of the closest arterial road. Although not designated as a source monitor, monitor G was located 2 km southwest of facilities emitting 0.30 and 0.41 tons/year (U.S. EPA, 2008a). Monitor H was sited on the grounds of the Northbrook Water Plant. Interstate I-94 curves around this site and was approximately 700 meters from the monitor to the east and around to the north. Figure 3-47 displays seasonal wind roses for Cook County. Wind patterns were quite variable during each season for this area. During the winter, winds mostly came from the west, with smaller contributions from the northwest, southwest, and south. In spring, measurable winds were omni-directional, with the highest winds coming from the south and northeast. Winds originated predominantly from the southwest and south during the summer, with measurable contributions from the northeast as well. In autumn, wind flow was predominantly from the south, but smaller contributions also came from the southwest, west, and northwest.

Figure 3-48 presents seasonal box plots of Pb concentration at the eight monitors located within Cook County. The maximum 95th percentile concentration on this plot was 0.14 $\mu g/m^3$, so the scale of this box plot makes the variability in these data appear wider than the data presented for Los Angeles County and Hillsborough/Pinellas Counties.

Monitor C was in closest proximity to the industrial steel facilities located in Lake County, IN. The average of concentrations measured at monitor C was 0.031 $\mu g/m^3$, with a median of 0.02 $\mu g/m^3$ and a maximum concentration of 0.31 $\mu g/m^3$. In winter, the 95th percentile of data was 0.14 $\mu g/m^3$. The higher values could potentially be attributed to transport of emissions; winds blow from the southeast roughly 10-15% of the time throughout the year. No other monitors in Cook County reported values above the level of the NAAQS.

Three “near-road” monitors, A, B, and D can be compared with the other monitors to consider the possibility of roadside resuspension of Pb dust from contemporaneous sources, as discussed in Section 3.2.2.6. It would be expected that resuspension would diminish with distance from the road. The 2 roadside monitors, A and B, reported average concentrations of 0.030 $\mu g/m^3$ and 0.024 $\mu g/m^3$, respectively. The median concentrations for monitors A and B were 0.02 $\mu g/m^3$. Fifteen percent of data were below the MDL for monitor A, and 25% were below the MDL for monitor B. Note that data obtained from monitor A may reflect industrial emissions as well. Monitor D was located roughly 60 meters from the closest interstate and 570 meters from the closest runway at O’Hare International Airport. The average concentration at this site was 0.012 $\mu g/m^3$, and 85% of data were below the MDL. Non-source monitors, E, F, G, and H had average concentrations of 0.011-0.017 $\mu g/m^3$. It is possible that the difference between Pb concentrations at monitors A and B and Pb concentrations at the other monitors was

related to proximity to the roadway, although this cannot be stated with certainty without source apportionment data to confirm or refute the influence of industrial plumes from Lake County, IN or local sources at each of the monitors.

Comparison among the monitor data demonstrates a high degree of spatial variability (Table 3-22). None of the source-oriented monitors were well correlated with each other. The highest correlation between source-oriented monitors occurred for monitors (A and B [R = 0.32, ρ = 0.26]). This might have reflected more substantial differences related to the additional influence of industrial sources nearby monitor A. Monitors (C and D) were uncorrelated with each other and with monitors (A and B), likely because their exposure to sources was substantially different. The source-oriented and non-source-oriented monitors were generally not well correlated. The highest Spearman correlation occurred between monitors D and H (ρ = 0.53), but Pearson correlation was much lower for this pair (R = 0.19). Both were located on the north side of Cook County, but monitor H was roughly 20 km northeast of monitor D. Winds blew from the southwest roughly 20-30% of the time throughout the year and from the northeast 20-25% of the time between the months of March and July, so the correlation may have been related to a common signal transported across both sites. Monitors B and F (R = 0.52, ρ = 0.46) were also moderately correlated. Monitor F is roughly 12 km northeast of monitor B, so the same common wind influence for monitors D and H may have also caused the moderate correlation between monitors (B and F). Monitor F was also moderately correlated with the other 3 non-source monitors (R = 0.42 to 0.54, ρ = 0.36 to 0.45), and the correlation between monitors (E and G) was moderate (R = 0.65, ρ = 0.40). The data from monitor H did not correlate well with those from monitors E and G. The non-source monitors were oriented from north to south over a distance of roughly 50 km in the following order: monitor H, monitor F, monitor G, and monitor E. The correlation pattern may have been related to distance between samplers. Monitor H was located in the suburb of Northbrook, monitors F and G were sited within the Chicago city limits, and monitor E was situated in a town near the south side of Chicago. Differences among land use may have been related to the lack of correlation of the monitor H data with those from monitors E and G. It is likely that data from monitor F was at times better correlated with monitors E and G and at other times with monitor H, since it had moderate correlation with all three other non-source monitors.

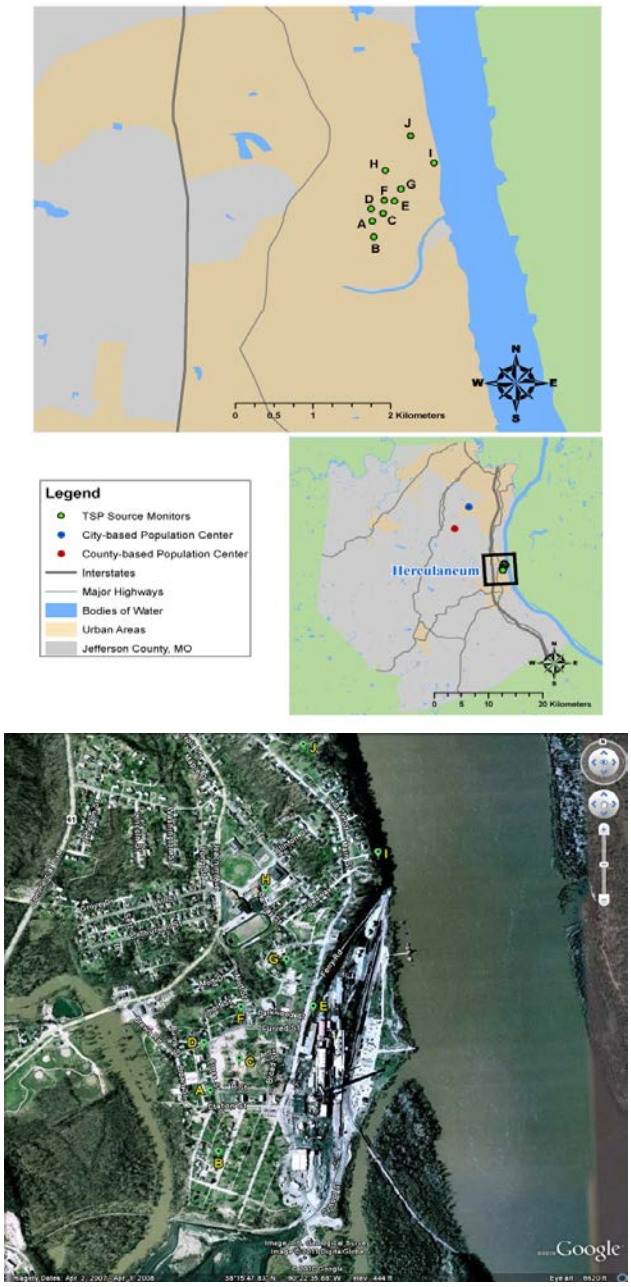
Figure 3-49 illustrates Pb monitor locations with Jefferson County, MO. Ten source-oriented monitors surrounded the Doe Run primary Pb smelter in Herculaneum, MO on the west and northwestern sides. The largest distance between these monitors was

approximately 1.5 km. Monitor E located on the Doe Run facility roughly 20 meters west of the nearest building. Monitors A, B, C, D, F, G, and H were all located approximately 200 meters west of the facility. Monitors D, E, and H were situated alongside service roads to the facility. Monitor I was sited 100 meters north of the smelter, and monitor J was located approximately 600 meters northwest of the facility. The Doe Run smelter was the only active primary smelter in the U.S. at the time of this review, and the facility was estimated to have emitted 41.1 tons Pb/yr (U.S. EPA, 2008f). Figure 3-50 displays seasonal wind roses for Jefferson County. During winter, predominant winds originated from the northwest, with a smaller fraction of calmer winds originating in the south-southeast. During the spring, the south-southeasterly winds became more prevalent with a measurable fraction of stronger winds still originating in the north-northwest. In the summer, winds were omni-directional and generally calmer. A slightly larger percentage came from the south compared with other wind directions. Autumn winds were most predominantly south-southeastern, with a smaller fraction from the west and northwest.

Figure 3-51 illustrates the seasonal distribution of concentrations at monitors A-J in Jefferson County. The annual average concentrations ranged from 0.18 to 1.36 $\mu g/m^3$ across the monitors. The maximum concentration was measured at monitor C to be 21.6 $\mu g/m^3$, which was 144 times higher than the level of the standard. For this monitor, the 25th percentile of the data was at the level of the standard. In general, median and 75th percentile concentrations were highest during the springtime and second highest during the fall. These seasons coincide with periods when the southeastern winds were stronger and more prevalent. Because the Doe Run facility had two 30-meter stacks (Bennett, 2007), it is possible that the Pb measured at the closer monitors were due to either fugitive emissions from the plant; or, if vechiles and ground equipment were operated nearby, the previously-deposited emissions from the plant were resuspended.

Spatial variability among the monitors is lower than at many sites, because the monitors are relatively close together and are located on one side of the same source (Table 3-23). Correlations range substantially ($R = -0.03$ to 0.96, $\rho = -0.04$ to 0.96). High correlations ($R \geq 0.75$, $\rho \geq 0.75$) occurred for monitors (A and C), (A and D), (C and D), (D and F), (E and F), (G and H), and (I and J). Monitors (A and C), (A and D), (C and D), (D and F), (E and F), and (G and H) are all within 250 meters of each other. For the highest correlation ($R = 0.96$, $\rho = 0.96$, [for monitors E and F]), monitor F is 250 meters directly east of monitor E. Low correlation ($R \leq 0.25$, $\rho \leq 0.25$) generally occurred when monitors B, I, and J were compared with monitors A, C, D, E, F, G, and H. Monitors B, I, and J were on the outskirts of the measurement area and so were likely oriented such that the southeasterly winds did not carry pollutants to these sites concurrently with the signal recorded by the other monitors.



Note: All monitors surround the Doe Run industrial facility. Top: Map view of all monitors in Jefferson County. Bottom: Satellite view of the monitors and the Doe Run facility.

Figure 3-52 illustrates Pb monitor locations in Cuyahoga County, OH. Five monitors are located within Cuyahoga County, three of which were designated by the Ohio EPA (OEPA) as source-oriented and the other two were non-source-oriented monitors. Monitors A, B, and C were all located within 1-10 km of six 0.1 tons/year source facilities and one 0.2 tons/year source (U.S. EPA, 2008g). Additionally, monitor B was located 30 meters north of the Ferro Corporation headquarters. This facility was stated in the 2005 NEI to have no emissions, but it was thought by the OEPA to be the source of exceedances at this monitor (U.S. EPA, 2008g). Monitor A was sited roughly 300 meters south of the Ferro Corporation facility. Monitor C was located 2.2 km west-northwest of the 0.5 tons/year Victory White Metal Co. facility. Monitor C was also roughly 250 meters southeast of Interstate I-490. Monitors D and E were designated as non-source-oriented monitors, although monitor D was just 600 meters further from the Victory White Metal facility than was monitor C. Monitor D was sited on a residential street located 50 meters north of Interstate I-490. Monitor E was located on the rooftop of a building within 20 meters of a four-lane arterial road. Figure 3-53 displays seasonal wind roses for Cuyahoga County. During winter, summer, and autumn, the predominant winds were from the southwest, with stronger winds recorded during the winter. In the spring, the strongest winds still emanated from the south-southwest, but measurable winds were also scattered from the northeast to the northwest.

Figure 3-54 illustrates the seasonal distribution of Pb concentration data at the five monitoring sites. The influence of southern winds, along with close proximity to a potentially-emitting facility, could have caused the elevated concentrations observed at monitor B (average: 0.10 μg/m^3). The 80th percentile of data was at the level of the NAAQS at this monitor, and during autumn the 60th percentile of data met the level of the NAAQS. The maximum concentration during fall and for the monitor year-round was 0.22 μg/m^3. Concentration data from all other monitors were below the level of the NAAQS. For monitor A, the average concentration was 0.025 μg/m^3, and the median

reached 0.04 μg/m^3 during the summer. Maximum concentration at this monitor was 0.07 μg/m^3. Concentrations at monitor C averaged 0.017 μg/m^3, and those at monitors D and E averaged 0.014 μg/m^3 and 0.013 μg/m^3, respectively. Maximum concentrations reached 0.04 μg/m^3 at all three monitors.

The level of spatial variability is illustrated by the intersampler correlations presented in Table 3-24. Monitors A and B appear to be anticorrelated (R = -0.06, ρ = -0.13). If the Ferro site was the dominant source in this area, then the anticorrelation was likely caused by the positioning of monitors A and B on opposite sides of that facility. At any given time, potential emissions from the Ferro plant may have affected monitors A and B at distinct times. Monitors C, D, and E correlated moderately to well with each other (R = 0.37 to 0.74, ρ = 0.67 to 0.77). Given that all 3 monitors are separated by roughly 2.8 km, it is possible that the relatively high correlations related to common sources, as suggested in the previous paragraph. Little correlation was observed between the source-oriented and non-source-oriented monitors.

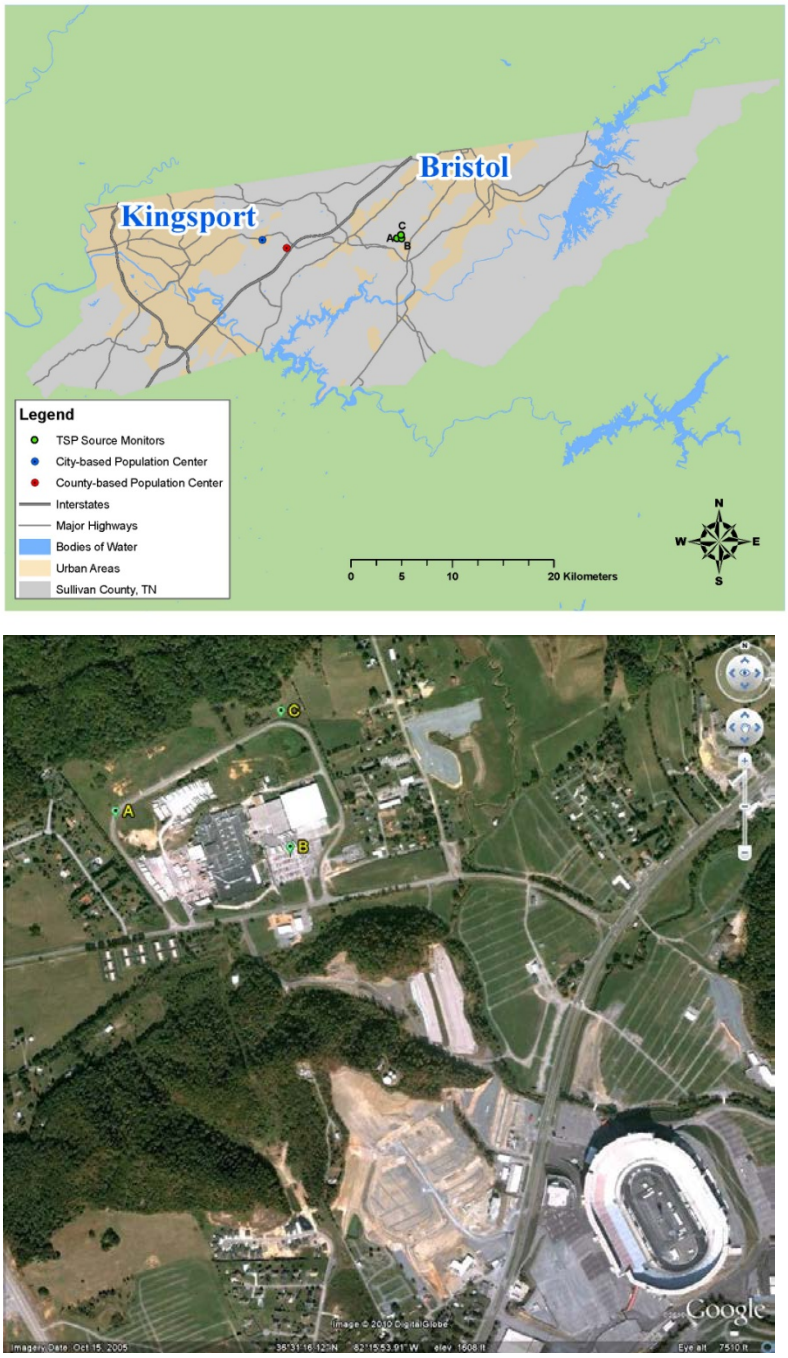
Figure 3-55 illustrates Pb monitor locations within Sullivan County, TN. Three source-oriented monitors were situated around an Exide Pb recycling facility emitting 0.78 tons/year (U.S. EPA, 2008h). Monitors A and C are positioned along the facility's service road and are approximately 100 meters and 200 meters away from the facility, respectively. Monitor A is directly next to the road, and monitor C is roughly 15 meters from the road. Monitor B is located in the facility's parking lot roughly 50 meters from the closest building. The facility and all three monitors are approximately 1.5 km northwest of the Bristol Motor Speedway and Dragway racetracks, which hosts a variety of auto races each year, including NASCAR, KART, and drag racing. Although the NASCAR circuit no longer uses tetraethyl Pb as an anti-knock agent in its fuel, some of the smaller racing circuits continue to do so. However, the speedway is rarely upwind of

the monitoring sites and so likely had minimal influence on the reported concentrations. Figure 3-56 displays seasonal wind roses for Sullivan County. During winter and spring, the predominant winds come from the southwest and west. In the summer, the percentage of wind coming from the west and southwest is roughly equal to that for wind coming from the east and northeast, although the easterly winds are calmer. During autumn, winds come predominantly from the northeast and east, although these winds tend to be calmer than those originating from the southwest and west.

The data presented in Figure 3-57 illustrates that concentrations above the level of the NAAQS occurred frequently at the monitors. The average concentrations at monitors A, B, and C were 0.11 $\mu g/m^3$, 0.051 $\mu g/m^3$, and 0.059 $\mu g/m^3$, respectively. Median concentrations were 0.08 $\mu g/m^3$, 0.03 $\mu g/m^3$, and 0.04 $\mu g/m^3$, respectively. The 75th percentile of year-round data at monitor A was at the level of the NAAQS, while the 95th percentile of data were below the NAAQS level for monitors B and C. The maxima at each monitor were 0.76 $\mu g/m^3$, 0.26 $\mu g/m^3$, and 0.43 $\mu g/m^3$ for monitors A, B, and C. The concentrations measured at monitor A tended to be higher because the predominant and stronger winds came from the southwest, so in many cases monitor A was upwind of the facility. It is possible that Pb that had either deposited or was stored in waste piles became readily resuspended by traffic-related turbulence and was measured at monitor A since that monitor was closest to the road. The slightly higher concentrations at monitor A compared with those from monitor C are consistent with the southwestern winds.

Not surprisingly, the correlations of monitor A with monitors B and C ($R = 0.06$ to 0.14, $\rho = -0.04$ to 0.13) were quite low (Table 3-25). The correlation between monitors B and C was moderate ($R = 0.31$, $\rho = 0.45$). It makes sense that the correlation for these monitors would be somewhat higher because they are both oriented to the east of the Pb recycling facility, although monitor C is to the northeast and monitor B to the east-southeast.



Note: Top: Map, bottom: Satellite image. Monitors A, B, and C surround the Exide Pb recycling facility. Just to the southeast is the Bristol motor speedway.

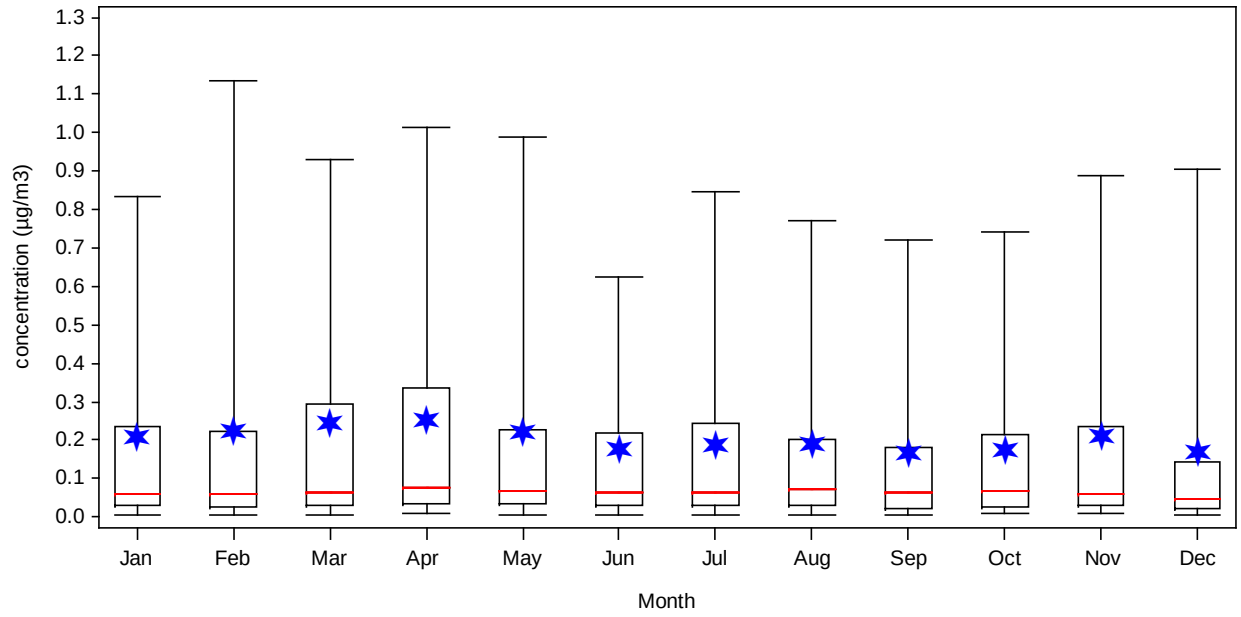
3.8.3 Seasonal Variation in Pb Concentrations

Monthly average Pb concentrations averaged over multiple sites and over 3 years from 2008-2010 are shown for Pb-TSP from source-oriented monitors (Figure 3-58), Pb-TSP from non-source-oriented monitors (Figure 3-59), Pb-PM_{10} (Figure 3-60), and Pb-$PM_{2.5}$ (Figure 3-61). For source-oriented Pb-TSP (Figure 3-58), monthly average concentrations were determined from between 146 and 154 samples in each month. For non-source-oriented TSP (Figure 3-59), monthly average concentrations were determined from between 141 and 151 samples in each month. A winter minimum was observed with December, January, and February exhibiting the three lowest monthly averages. In both cases, there is little seasonal variation. Minor variations in monthly averages are probably driven by exceptional events. Monthly median concentrations are very similar for all months.



Note: Box and whisker plots are used for each month, with the box comprising the interquartile range of the data and the whiskers comprising the range within the 5th to 95th percentiles. The median is noted by the red line, and the blue star denotes the mean.

Note: Box and whisker plots are used for each month, with the box comprising the interquartile range of the data and whiskers comprising the range from 5th to 95th percentiles. The median is noted by the red line, and the blue star denotes the mean.

Figure 3-61 Monthly Pb-$PM_{2.5}$ average (µg/m^3) over 12 months of the year, 2007-2009.

For both Pb-PM_{10} (Figure 3-60) and Pb-$PM_{2.5}$, (Figure 3-61) there is also little seasonal variation, with minor fluctuations in monthly averages probably driven by exceptional events, and similar monthly median concentrations for all months. Pb-PM_{10} monthly average concentrations were determined from between 100 and 109 samples and Pb-$PM_{2.5}$ from between 866 and 1,034 samples each month.

3.8.4 Size Distribution of Pb-bearing PM

Table 3-26 presents data for co-located Pb-TSP, Pb-PM_{10}, and/or Pb-$PM_{2.5}$ monitors. Table 3-27 contains metadata for studies in Section 3.5.3 involving size distribution data, and Table 3-28 contains the size distribution data for those studies. At times, the data were extracted from figures in the original references.

Table 3-26 Correlations and average of the concentration ratios for co-located monitors, TSP versus PM_{10}, TSP versus $PM_{2.5}$, and PM_{10} versus $PM_{2.5}$.

			Years	Corr	Avg Ratio	Years	Corr	Avg Ratio	Years	Corr	Avg Ratio
Site ID*	CBSA	Land Type	PM_{10}: TSP			$PM_{2.5}$: TSP			$PM_{2.5}$: PM_{10}

*Note: For comparability, comparisons are limited to monitors where all samples were above the MDL, at least 30 co-located samples were obtained, and both monitors reported data at standard temperature and pressure.

Table 3-27 Metadata for studies of Pb-PM size distribution.

Reference	Location	Nearest source	Proximity to source	Sampling dates
Yi et al. (2006)	Jersey City, NJ- an urban/industrial area New Brunswick, NJ- a suburban area	Jersey City- near Manhattan, NJ Turnpike, Hudson River- high gas/oil consumption for industry/domestic heating, heavy gasoline & diesel powered vehicles and ship traffic from harbor. New Brunswick- near NJ parkway and Garden State Parkway	Close	ASD measurements: June 10-20, 2002
Bein et al. (2006)	Pittsburg, PA	Article does not describe sources; other articles also use data from Pittsburgh Air Quality Study (PAQS) and may have more info on sources		July 2001-September 2002
Pekey et al. (2010)	Kocaeli, Turkey	Kocaeli is a very industrialized and urbanized region in Turkey; sources include a large refinery, a petrochemical complex, a hazardous waste incinerator and industry operations for textile, machine, mine, metal, food, automotive, paper, chemistry, wood, petroleum, tanning, and coal sectors, plus heavy traffic		
Singh et al. (2002)	Downey, CA- a city in Los Angeles County along "Alameda corridor" joining coastal area to downtown LA Riverside, CA- an inland county east of LA	Downey- a "source" site affected by fresh PM emissions from nearby oil refineries, industry, and heavy diesel emissions Riverside- a "receptor" site affected by aged PM emissions including high vehicle emissions in LA	Downey: 10 km downwind of refineries; 2-4 km from Interstates I-710 and I-605 Riverside- 70 km east of downtown LA	Downey: September 2000-January 2001 Riverside: February 2001-June 2001
Dall'Osto et al. (2008)	U.K. national air quality monitoring station in Port Talbot, U.K.	One of the U.K.'s largest integrated steelworks; near major roadways; (Table 1 of this study describes the plants, operations, emission types, and emission components for steelwork sources)	Monitoring site next to steelwork	April 24-May 5, 2006
Weitkamp et al. (2005)	Coking facility near Pittsburgh, PA	Large coking facility that converts 6 million tons of coal to 4 million tons of metallurgic coke every year	Sampling site downwind, directly across river from coke facility(~400m)	August 22-September 5, 2002
Pekey et al. (2010)	Indoor/outdoor sample points for 15 homes in Kocaeli, Turkey	Kocaeli is a very industrialized and urbanized region in Turkey; sources include a large refinery, a petrochemical complex, a hazardous waste incinerator and industry operations for textile, machine, mine, metal, food, automotive, paper, chemistry, wood, petroleum, tanning, and coal sectors, plus heavy traffic	15 Kocaeli homes chosen as representative sample; 10 close to high traffic roads, 5 near low/moderate traffic roads	Summer: May 31-June 29, 2006 Winter: December 16-January 20, 2007

Reference	Location	Nearest source	Proximity to source	Sampling dates
Sabin et al. (2006b)	Near Interstate I-405 between Sunset Blvd and Wilshire Blvd, Los Angeles, CA	Heavy traffic on Interstate I-405 Freeway	UP: 150m upwind of Interstate I-405 (background) DW1: 10m downwind DW2: 150m downwind DW3: 450m downwind	April 13-May 1, 2004
Song and Gao (2011)	Carlstadt, NJ	Heavy traffic on NJ Turnpike	~5m from roadside of the highway	Winter: December 2007-February 2008 Summer: July 2008
Zereini et al. (2005)	3 Sites in Frankfurt, Germany with different traffic densities	Vehicle emissions	Site 1: next to main street with 32500 cars/day Site 2: next to side street with <1000 cars/day Site 3: large garden 8km NW of city	August 2001 to July 2002
Lough et al. (2005)	Two road traffic tunnels in Milwaukee, WI	Traffic emissions	5 m upwind from entrance (inside tunnel); 15 m upwind from tunnel exit	Summer: July 31-August 28, 2000 Winter: December 13-January 17, 2001
Hays et al. (2011)	20m downwind of Interstate I-440 highway in Raleigh, NC	Traffic emissions from highway	20 m downwind	July 26-31 and August 3-10, 2006
Chen et al. (2010b)	Roadside site and site inside highway tunnel in Taipei, Taiwan	Vehicle emissions	Roadside: sidewalk 4m from road Tunnel: relay station in tunnel 1.4km from outlet; 2 m from traffic lane	January to December 2008
Birmili et al. (2006)	Remote background: Mace Head atmospheric research station in Connemara, Ireland Urban background: University of Birmingham campus, U.K. Roadside: A38 Bristol Road, Birmingham, U.K. Road Tunnel: Queensway underpass in Birmingham, U.K.	Traffic emissions	Remote background: Urban background: at least 100m from road traffic Roadside: 4 m from traffic Road Tunnel: 30 m from tunnel exit	Remote background: August 8-28, 2002 Urban background: April 23-October 7, 2002 Roadside: July 8-12, 2002 Road Tunnel: July 2, 2002
Bruggemann et al. (2009)	Roadside in Dresden, Germany	Traffic emissions from busy street (traffic density~55,000 per day; 8% trucks), tramline, railway station	Next to road, near tramline crossing, 200 m to railway station	September 2003-August 2004
Harrison et al. (2003)	Roadside in Birmingham, U.K.	Traffic emissions from A38	9m from road	October 26, 2000 to January 17, 2001

Reference	Location	Nearest source	Proximity to source	Sampling dates
Wang et al. (2006d)	Suburb of Kanazawa, Japan- a western coastal city; the largest in Hokuriku region of Japan	Emissions from road traffic, nearby incinerators and electricity generation plants, and sea salt	Next to road; ~5km from incinerators and electricity generation plants; situated on west coast	May-June 2003
Martuzevicius et al. (2004)	9 Locations in Cincinnati, Ohio metropolitan area	Vehicle emissions from Cincinnati highway network; emission from industry (233 facilities within municipal area limits)	11 Sites- varying distance to linear and point sources; distance to major highways ranges from 210 m to 4,590 m	December 2001-November 2002
Moreno et al. (2008)	3 Sampling sites in Mexico City (Mexico) Metropolitan Area: 1 Site in the industrial center (T0), 1 Site NE outside city limits (T1), and 1 Rural site north of city (T2)	Urban pollution sources- traffic emissions, industry	3 Sites with varying relation to "Mexico urban plume" by distance, wind direction	March 2006
Goforth and Christoforou (2006)	Lake Hartwell, GA (rural southeast U.S.)			February-March 2003
Makkonen et al. (2010)	Virolahti EMEP station, Finland	European Route E18 (3,000 vehicles/day)	5 km	August 2007
Wojas and Almquist (2007)	Oxford, OH and other towns in Greater Cincinnati region	Transportation, manufacturing processes, and coal-fired power plants	~80 km to northwest Cincinnati	January to December 2005
Lin et al. (2005)	Roadside in city in southern Taiwan	Traffic emissions (avg traffic load = 72,000 vehicles/day), Pingtung Industrial Park (146 factories), Nearby crematory	10 m from road, 2 km from industrial park (146 factories, i.e., electron apparatus, metal, and food manufacturing), 1 km from crematory	February to April 2004
Csavina et al. (2011)	Main sampling site in Winkelman, Arizona at Hayden High School	Nearby an active mining and smelting site in Hayden, Arizona	2km from mine tailings pile; 1km from smelting operations, main smoke stack, and slag pile	December 2008-November 2009

Reference	Location	Nearest source	Proximity to source	Sampling dates
Fang and Huang (2011)	3 Sites in central Taiwan: A school (Hung-kuang), A wetland (Gaomei in Taichung), An industrial site (Quan-xing)	Emissions from vehicle traffic and industry	Hung-kuang (HK): in residential area 2 km from major expressway Gaomei in Taichung (GM): 300 hectare wetland with coal combustion-based Taichung Thermal Power Plant (located along the coast of the west side of the sampling site) Quan-xing (QX): town with lots of industry including metal manufacturing, textiles, petroleum and coal products	November 2010-December 2010
Lim et al. (2006)	7 Sites around Los Angeles, CA, including 6 urban watershed sites and one non-urban coastal watershed.	Not stated	-	August, 2002 – June, 2003

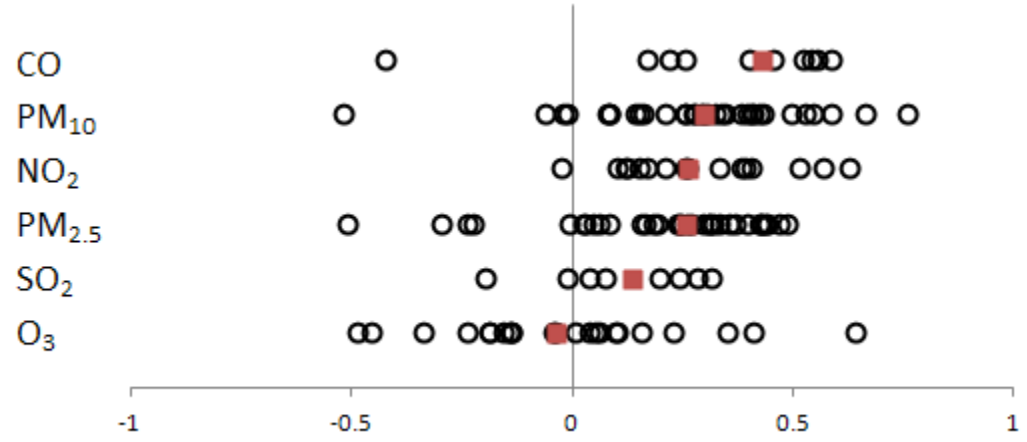
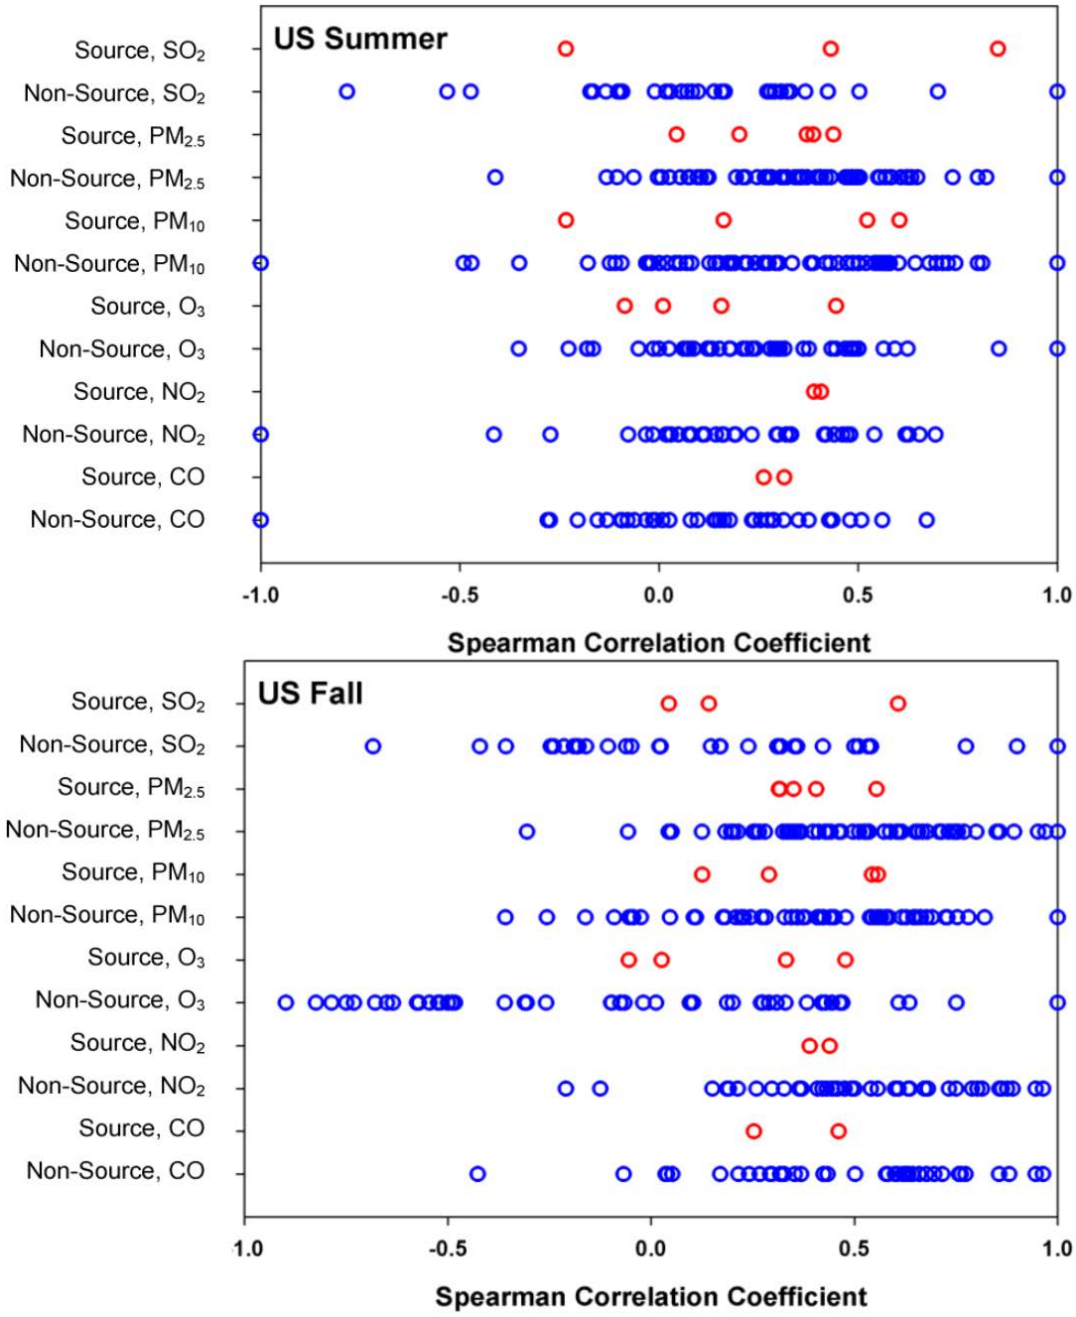
3.8.5 Pb Concentration in a Multipollutant Context



Note: Correlations were calculated from available data when data were above MDL and there were at least 30 data pairs available for comparison.

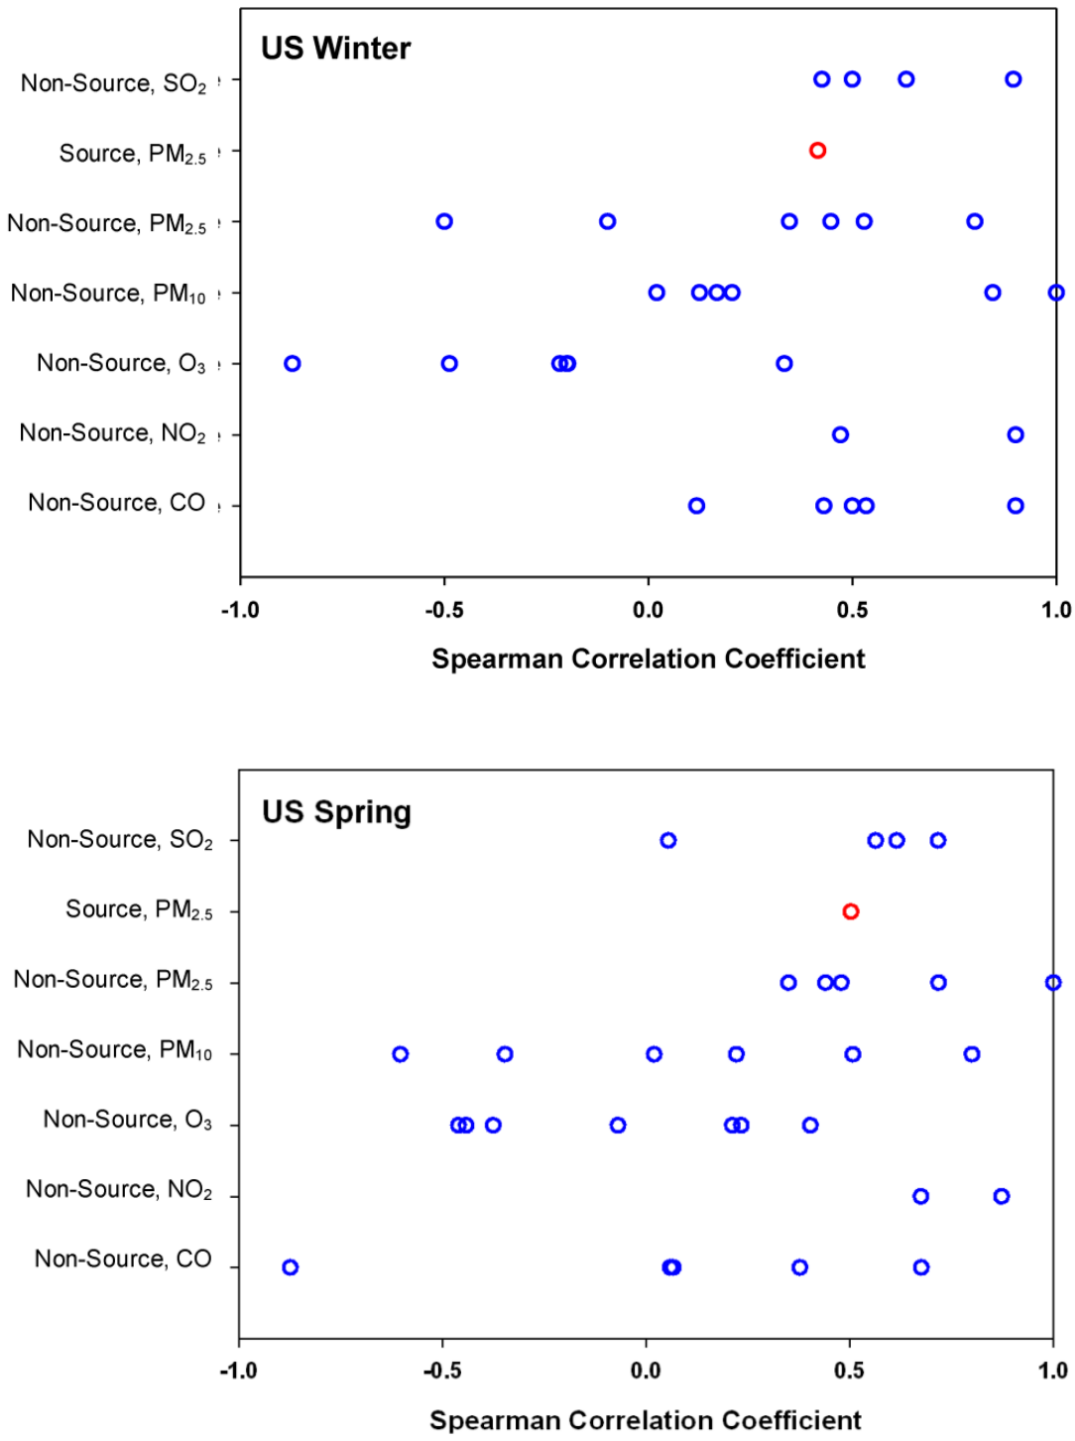
Correlations for individual sites are shown with black open circles, while median correlations are illustrated with a red square.

Figure 3-62 Spearman correlations of monitored non-source Pb-TSP concentration with daily averages of copollutant concentrations, 2008-2010.



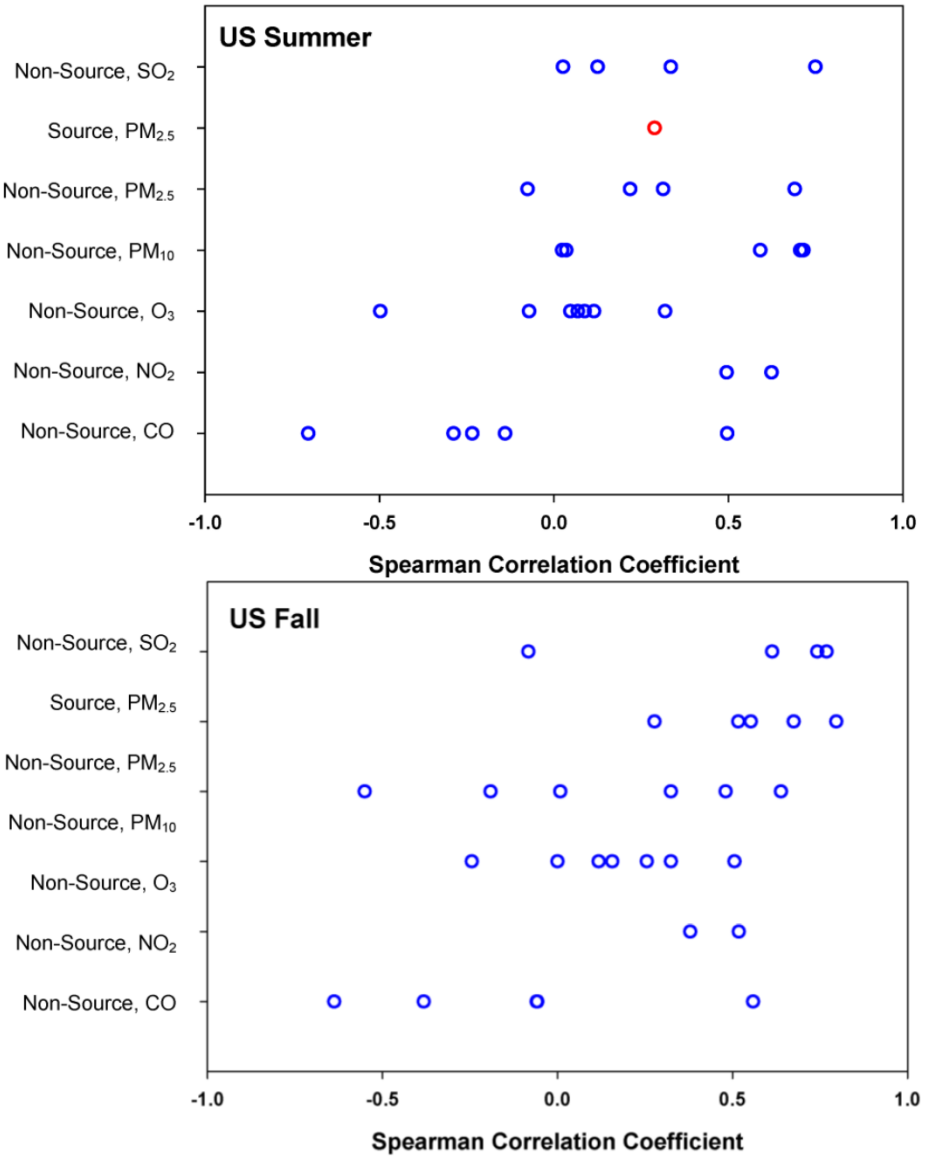
Note: Top panel: Summer; Bottom panel: Fall.

Figure 3-63 Seasonal correlations of monitored Pb-TSP concentration with copollutant concentrations, 2007-2008.



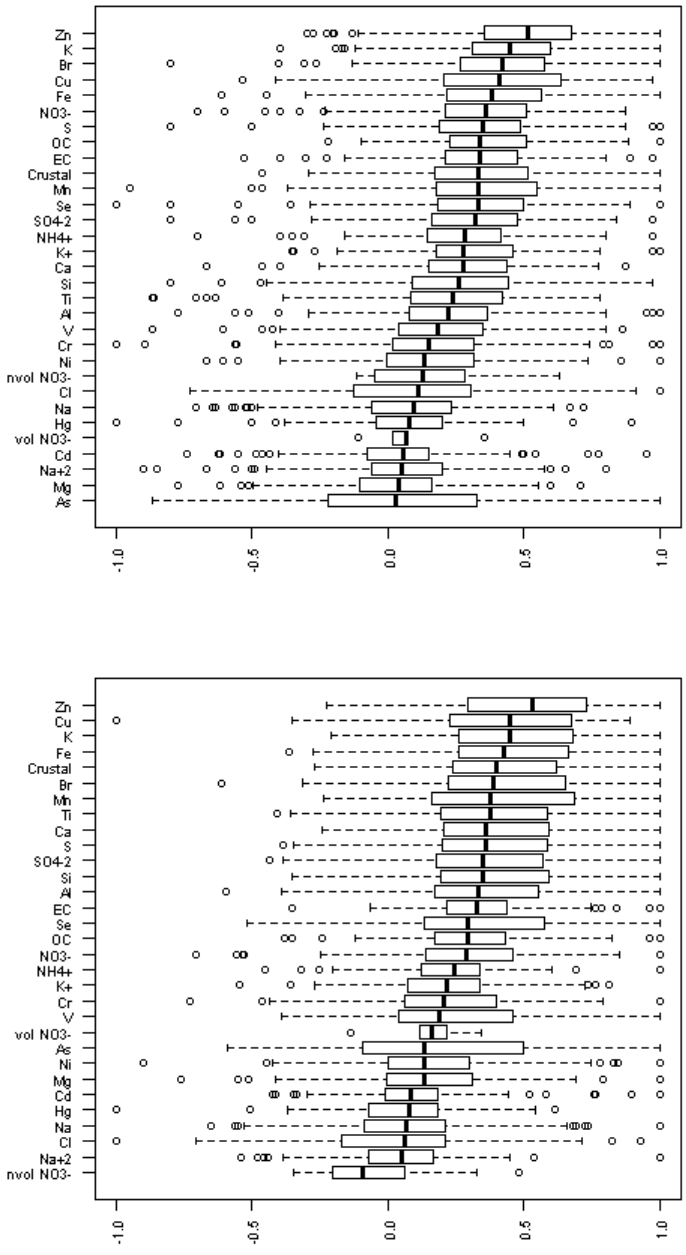
Note: Top panel: Winter; Bottom panel: Spring.

Figure 3-64 Seasonal correlations of monitored Pb-TSP concentration with copollutant concentrations, 2009.



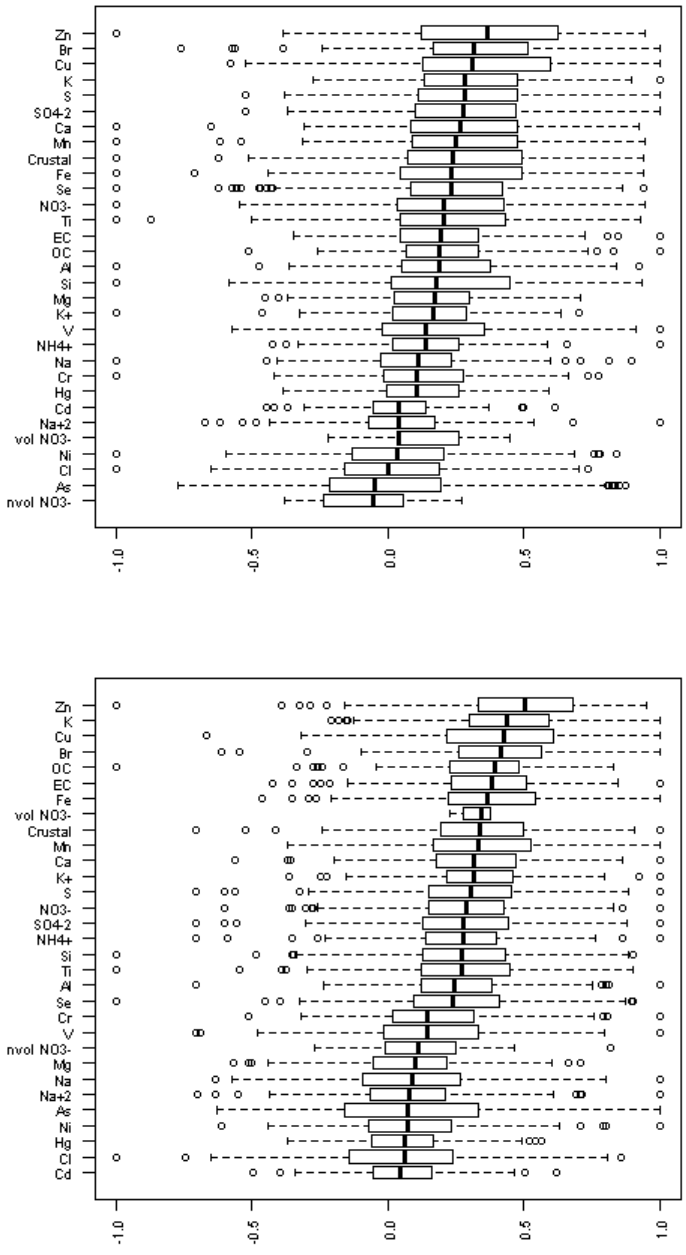
Note: Top panel: Summer; Bottom panel: Fall.

Figure 3-65 Seasonal correlations of monitored Pb-TSP concentration with copollutant concentrations, 2009.



Top panel: Winter; Bottom panel: Spring.
Note: "nvol" = non-volatile, "vol" = volatile, and organic carbon (OC) samples were blank-adjusted.

Figure 3-66 Seasonal correlations of monitored Pb-$PM_{2.5}$ concentration with copollutant concentrations, 2007-2009.



Top panel: Summer; Bottom panel: Fall.
Note: "nvol" = non-volatile, "vol" = volatile, and organic carbon (OC) samples were blank-adjusted.

Figure 3-67 Seasonal correlations of monitored Pb-$PM_{2.5}$ concentration with copollutant concentrations, 2007-2009.

Table 3-29 Copollutant exposures for various trace metal studies.

4 EXPOSURE, TOXICOKINETICS, AND BIOMARKERS

4.1 Exposure Assessment

The purpose of this section is to present recent studies that provide insight about human exposure to Pb through various pathways. Pb is considered to be a multimedia contaminant with multiple pathways of exposure. The relative importance of various media in affecting Pb exposure changes with source strength and location, location and time activity of the exposed individuals, behavior of the exposed individuals, and risk factors such as age and socioeconomic factors (risk factors are discussed in detail in Chapter 5). Blood Pb and bone Pb biomarkers (discussed in Sections 4.3, 4.4, and 4.5), are often used to indicate composite Pb exposure resulting from multiple media and pathways of exposure.

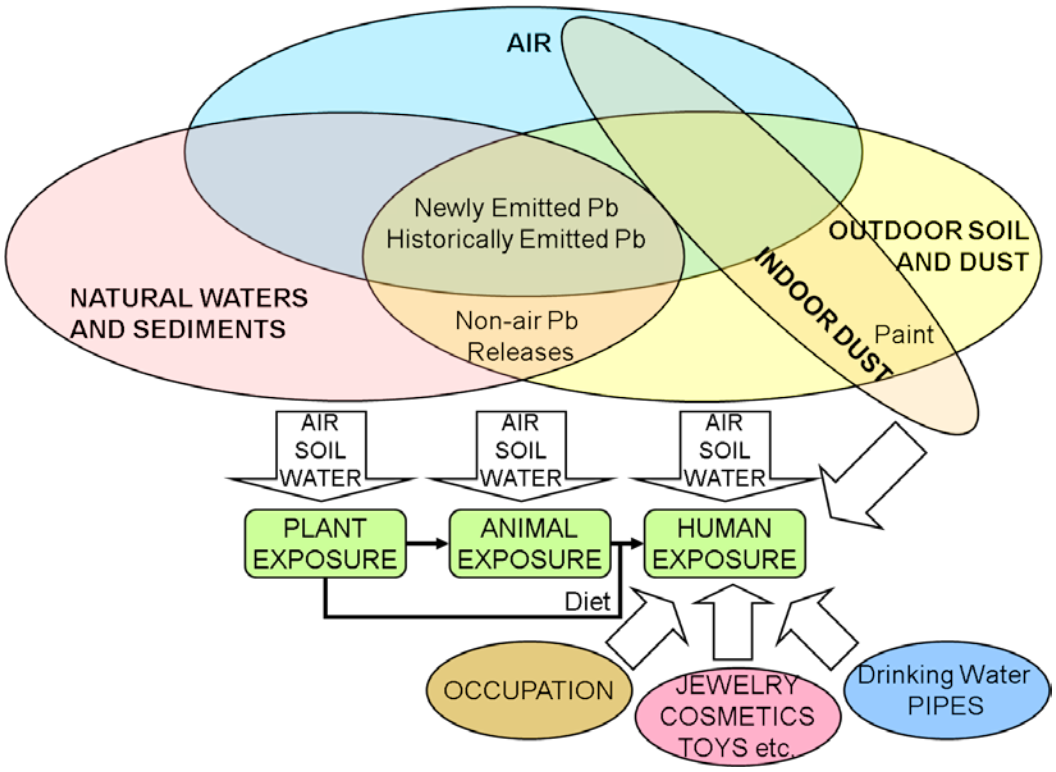
The recent information provided here builds upon the conclusions of the 2006 Pb AQCD (U.S. EPA, 2006b), which found that air Pb concentrations and blood Pb levels have decreased substantially following the restrictions on Pb in on-road vehicle gasoline, Pb in household paints, the use of Pb solder, and reductions in industrial Pb emissions that have occurred since the late 1970s. Nevertheless, detectable quantities of Pb have still been observed to be bioaccessible in various media types. It was reported in the 2006 Pb AQCD (U.S. EPA, 2006b) that airborne maximum quarterly Pb concentrations in the U.S. were in the range of 0.03-0.05 $\mu g/m^3$ for non-source-oriented monitors for the years 2000-2004 and were 0.10-0.22 $\mu g/m^3$ for source-oriented monitors during that time period, while blood Pb levels reached a median of 1.70 μg/dL among children (1-5 years of age) in 2001-2002. It was also observed that Pb exposures were associated with nearby industrial Pb sources, presence of Pb-based paint, and Pb deposited onto food in several of the studies described in the 2006 Pb AQCD.

4.1.1 Pathways for Pb Exposure

Pathways of Pb exposure are difficult to disentangle because Pb has multiple sources in the environment and passes through various environmental media. These issues are described in detail in Sections 3.2 and 3.3. Air-related pathways of Pb exposure are the focus of this ISA. Pb can be emitted to air, soil, or water and then cycle through any or all of these media. In addition to primary emission of particle-bound or gaseous Pb to the atmosphere, Pb can be resuspended to the air from soil or dust. Additionally, Pb-bearing PM can be deposited from the air to soil or water through wet and dry deposition. Air-

related Pb exposures also include inhalation and ingestion of Pb-contaminated food, water or other materials following atmospheric deposition of Pb; these exposures include dust and soil via hand-to-mouth contact. In general, air-related pathways include those pathways where Pb passes through ambient air on its path from a source to human exposure. Some non-air-related exposures of Pb include ingestion of indoor Pb paint, Pb in diet as a result of inadvertent additions during food processing, and Pb in drinking water attributable to Pb in distribution systems, as well as other generally less prevalent pathways.

The complicated nature of Pb exposure is illustrated in Figure 4-1, in which the Venn diagram depicts how Pb can cycle through multiple environmental media prior to human exposure. The "air/soil/water" arrows illustrate Pb exposures to plants, animals, and/or humans via contact with Pb-containing media. The exposures are air-related if Pb passed through the air compartment. When animals consume plant material or water exposed to Pb that has at some point passed through the air compartment, and when human diet includes animals, plants or drinking water exposed to Pb that has passed through the air compartment, these are also considered air-related Pb exposures. As a result of the multitude of possible air-related exposure scenarios and the related difficulty of constructing Pb exposure histories, most studies of Pb exposure through air, water, and soil can be informative to this review. Figure 4-1 also illustrates other exposures, such as occupational exposures, contact with consumer goods in which Pb has been used, or ingestion of Pb in drinking water conveyed through Pb pipes. Most Pb biomarker studies do not indicate speciation or isotopic signature, and so exposures that are not related to Pb in ambient air are also reviewed in this section because they can contribute to Pb body burden. Many of the studies presented in the subsequent material focus on observations of Pb exposure via one medium: air, water, soil and dust, diet, or occupation.



Note: The Venn diagram is used to illustrate the passage of Pb through multiple environmental media compartments through which exposure can occur.

Figure 4-1 Conceptual model of multimedia Pb exposure.

The relative importance of different sources or pathways of potential exposure to Pb in the environment is often difficult to discern. Individual factors such as home environment, location, and risk factors (described in more detail in Chapter 5) may influence exposures. The National Human Exposure Assessment Survey (NHEXAS) study sampled Pb, as well as other pollutants and VOCs, in multiple exposure media from subjects across six states in EPA Region 5 (Illinois, Indiana, Michigan, Minnesota, Ohio, and Wisconsin) (Clayton et al., 1999) as well as in Arizona (O'Rourke et al., 1999) and Maryland (Egeghy et al., 2005). Results from NHEXAS indicate that personal exposure concentrations of Pb are higher than indoor or outdoor concentrations of Pb, perhaps suggesting a personal cloud effect; see Table 4-1. Pb levels in windowsill dust were higher than Pb levels in surface dust collected from other surfaces. Clayton et al. (1999) suggested that higher windowsill levels could be attributed to the presence of Pb-based paint and/or to accumulation of infiltrated outdoor Pb-bearing PM. Pb levels in food were higher than in beverages, and Pb levels in standing tap water (also referred to as "first flush" or "first draw") were higher than Pb levels obtained after allowing water to run for three minutes to flush out pipes. Layton and Beamer (2009) estimated that 34-66% of Pb in floor dust was tracked in from outdoors and originated as ambient air Pb, based on

1992 levels in Sacramento; in 1992, phase-out of Pb usage in gasoline was near complete, but industrial emissions were still higher than current levels; see Section 3.2.

Table 4-1 Estimates of Pb measurements for EPA Region 5 from the NHEXAS study.

Medium[a]	N	Percentage above LOD[b] (CLs)[c]	Mean (CLs)[c]	50th (CLs)[c]	90th (CLs)[c]
Personal air (ng/m^3)[d]	167	81.6 (71.3; 92.0)	26.83 (17.60; 36.06)	13.01 (11.13; 18.13)	57.20 (31.18; 85.10)
Indoor air (ng/m^3)[d]	213	49.8 (37.2; 62.3)	14.37 (8.76; 19.98)	6.61 (4.99; 8.15)	18.50 (12.69; 30.31)
Outdoor air (ng/m^3)[d]	87	73.8 (56.3; 91.3)	11.32 (8.16; 14.47)	8.50 (7.14; 10.35)	20.36 (12.60; 34.91)
Surface dust (ng/cm^2)	245	92.1 (87.4; 96.8)	514.43 (-336.6; 1365.5)	5.96 (3.37; 10.94)	84.23 (26.52; 442.63)
Surface dust (mg/kg)	244	92.1 (87.4; 96.8)	463.09 (188.15; 738.04)	120.12 (83.85; 160.59)	698.92 (411.84; 1,062.8)
Window sill dust (ng/cm^2)	239	95.8 (92.5; 99.0)	1,822.6 (481.49; 3,163.6)	16.76 (10.44; 39.41)	439.73 (106.34; 4,436.2)
Window sill dust (mg/kg)	239	95.8 (92.5; 99.0)	954.07 (506.70; 1,401.4)	191.43 (140.48; 256.65)	1,842.8 (1,151.3; 2,782.5)
Standing tap water (µg/L)	444	98.8 (97.6; 100.0)	3.92 (3.06; 4.79)	1.92 (1.49; 2.74)	9.34 (7.87; 12.35)
Flushed tap water (µg/L)	443	78.7 (70.7; 86.7)	0.84 (0.60; 1.07)	0.33 (0.23; 0.49)	1.85 (1.21; 3.04)
Solid food (µg/kg)	159	100.0 (100.0; 100.0)	10.47 (6.87; 14.07)	6.88 (6.44; 8.04)	14.88 (10.78; 19.08)
Beverages (µg/kg)	160	91.5 (85.2; 97.8)	1.42 (1.13; 1.72)	0.99 (0.84; 1.21)	2.47 (2.06; 3.59)
Food + Beverages (µg/kg)	156	100.0 (100.0; 100.0)	4.48 (2.94; 6.02)	3.10 (2.66; 3.52)	6.37 (4.89; 8.00)
Food intake (µg/day)	159	100.0 (100.0; 100.0)	7.96 (4.25; 11.68)	4.56 (3.68; 5.36)	12.61 (9.27; 16.38)
Beverage intake (µg/day)	160	91.5 (85.2; 97.8)	2.15 (1.66; 2.64)	1.41 (1.18; 1.60)	4.45 (3.15; 5.65)
Food + Beverage intake (µg/day)	156	100.0 (100.0; 100.0)	10.20 (6.52; 13.89)	6.40 (5.21; 7.78)	16.05 (13.31; 18.85)
Blood (µg/dL)	165	94.2 (88.2; 100.0)	2.18 (1.78; 2.58)	1.61 (1.41; 2.17)	4.05 (3.24; 5.18)

Note: EPA Region 5 includes six states: Illinois, Indiana, Ohio, Michigan, Minnesota, and Wisconsin. Participants were enrolled using a stratified, four-stage probability sampling design, and submitted questionnaire and physical measurements data. Summary statistics (percentage above limit of detection (LOD), mean, median, 90th percentile) were computed using weighted sample data analysis. The estimates apply to the larger Region 5 target population (all non-institutionalized residents residing in households).

[a]Estimates for indoor air, outdoor air, dust media, and water media apply to the target population of Region 5 households; estimates for other media apply to the target population of Region 5 residents.

[b]Percentage of the target population of residents (or households) estimated to have Pb levels above limit of detection (LOD).

[c]The lower and upper bounds of the 95% confidence limits (CL) are provided.

4.1.1.1 Particle Size Distributions for Airborne-Pb, Dust-Pb, and Soil-Pb

The size distribution of ingestible dust particles differs from the size distribution of inhalable ambient air Pb particles and therefore cannot be directly compared. The inhalability of airborne PM is a gradually decreasing function of particle size. Inhalability criteria established from experimental data, obtained at wind speeds of 1-8 meters/second, describe PM inhalability of 77% for particles <10 μm (d_{ae}, aerodynamic diameter). Inhalability of particles ranging in size from 40 to 100 μm d_{ae} is 50%; above 100 μm, inhalability data are lacking (Soderholm, 1989; ACGIH, 1985). The particles that are not inhaled may settle to surfaces, making them available for subsequent ingestion. The size distribution of soil and house dust particles tends to be much larger than airborne PM. Que Hee et al. (1985) and U.S. EPA (1990b) observed that 50% or more of the mass of house dust tends to be comprised of particles smaller than 150 μm. Gulson et al. (1995b) observed that the mode of the Pb house dust size distribution was in the 38-53 μm range; they did not report the overall house dust size distribution. Given the house dust Pb size distributions documented, dust Pb brought into homes with foot traffic may be aerosolized but is likely to stay airborne for only a few seconds, since particles larger than $PM_{2.5}$ tend to settle from the air quickly; see Section 3.3.1.3 and Section 4.1.3.1. Siciliano et al. (2009) observed different size distributions for different types of soils: agricultural sites had median soil Pb of 34 μm, and brownfields had median soil Pb of 105 μm. These observations of larger particle sizes for soil and dust Pb support the notion that exposure to Pb in dusts and soils would occur by ingestion rather than inhalation following resuspension.

The main pathway for Pb ingestion by children is by hand to mouth contact (Lanphear et al., 1998). In a playground environment in London, U.K., Duggan et al. (1985) reported that hand to mouth transfer was effectively limited to particles smaller than 10 μm, even when the soil itself exhibited a much larger particle size distribution. More recently, Yamamoto et al. (2006) reported for a cohort of children in Kanagawa Prefecture, Japan (greater Tokyo area) that the mode of size distributions of particles adhering to children's hands was 39 ± 26 μm, with the upper tail ranging from 200-300 μm. Kissel et al. (1996) measured three size fractions of soil adhered to a hand via a hand press: ≤ 150 μm, 150-250 μm, and ≥ 250 μm and observed that, when soil was dry (<2% moisture content), 43%-69% of the soil was in the smallest fraction. When the moisture content was higher than 2%, 28-81% of the adhered soil was in larger than 250 μm. Percentage and mass adhered per area (mg/cm^2) depended on soil type, with wet sand and loamy sand adhering more to hands than sandy loam or silt loam. For dry soil, silt loam mass produced the largest adherence in terms of mass per area. Differences among the size

distribution results may be related to differences in the soil type, soil moisture levels between the locations, and/or to differences between the analytical methods used to measure size distribution; Duggan and Inskip (1985) used optical microscopy of the dust wipes, while Yamamoto et al. (2006) used a laser scattering device measuring sampled particles suspended in an aqueous solution. Siciliano et al. (2009) regressed adhered average soil size on hands bulk soil particle size and found a log-log relationship with $\beta = 0.66$ using both brownfield and agricultural soils; the proportion of soil adhered depended on organic content.

Several studies have found that Pb is enriched in the smaller fractions of the soil or house-dust size distribution. Davies and White (1981) observed that enrichment decreased linearly with increasing dust size bin, with dust particles smaller than 64 μm having a Pb concentration of 76.1 mg/kg and particles in the 1,000-2,000 μm size range having a Pb concentration of 16.4 mg/kg. Sheets and Bergquist (1999) also found that Pb content decreased with increasing particle size. More recently, Ljung et al. (2006) investigated childhood exposures to trace metals on playgrounds in Uppsala, Sweden and observed that the Pb content in soil in the <50 μm size fraction was 1.5 times higher than that in the >4 mm or 50-100 μm size fractions. Sheppard et al. (1995) measured enrichment in different types of soils (sand and clay) and found that enrichment was substantially higher in the sand.

Studies focusing on particle size distributions of house dust adhered to the hands are lacking. Ingestion of house dust has been reported to be the major source of Pb intake during early childhood (Lanphear et al., 2002). If a similar particle size distribution holds for household dust, then ingestion of indoor Pb of atmospheric origin could also be strongly dependent on dust particle size. Therefore, larger particles of atmospheric origin, which may not be considered relevant for exposure by inhalation exposure, are still relevant for Pb exposure by ingestion. However, no studies in the literature have presented information on the relative contributions of Pb from different PM size fractions to blood Pb concentrations.

It should be noted that different measurement techniques are used for different environmental media. For example, ambient air Pb-PM size distribution is measured by one of the non-FRM instruments such as a MOUDI, described in Section 3.4, and its measurement is subject to errors specific to the technique. Dust and soil size distribution are typically measured with graduated sieves, and errors associated with these methods occur more often in the smaller size fractions that are subject to agglomeration and clogging if the particle shape is nonspherical.

4.1.1.2 Estimating Pb Exposure in the Integrated Exposure Uptake Biokinetic (IEUBK) Model

Several studies have used a combination of measured values and default model values to represent exposures and determine their relative contributions to blood Pb. For example, Cornelis et al. (2006) used the Integrated Exposure Uptake Biokinetic model (IEUBK), described in detail in the 2006 Pb AQCD (U.S. EPA, 2006b) to model children's exposures to Pb emissions from a non-ferrous smelter in Hoboken, Belgium. In deriving the model input (annual averages) for ambient air Pb concentration, as well as soil and dust, they employed weighting based on children's time spent in different locations in the study area and air, soil and indoor dust measurements in those areas. In their results for the area of the smelter, the ingestion of dust and soil pathways accounted for more than 70% of the exposure, while the inhalation pathway accounted for less than 2%. Similarly, Carrizales et al. (2006) analyzed exposures to children living near a copper (Cu) smelter in San Luis Potosi, Mexico. They employed the IEUBK default options for assignment of Pb dust concentration as 70% of the soil Pb concentration, while air Pb concentration was assigned based on measurements by the Mexican government. Based on these assumptions, they attributed 87% of blood Pb to soil and dust exposure. These studies did not estimate the air Pb contribution to the soil/dust Pb concentrations and consequently did not estimate the portion of the ingestion pathway that derives from ambient air Pb.

Appendix I of the 2007 Pb Risk Assessment (U.S. EPA, 2007f) provides estimates of the contribution of various pathways to the blood Pb of children simulated in several case studies. Simulations provided estimates of contributions from outdoor ambient air Pb by inhalation and by ingestion of indoor dust, including the fraction of indoor dust Pb associated with recent penetration of ambient air Pb into the residence. Although ambient air Pb may also contribute to Pb ingestion through other pathways (i.e., diet, soil), data and tools to support a simulation of the linkage between air Pb concentrations and concentrations in other media were limited. Accordingly, Pb concentrations pertaining to other pathways (e.g., diet, outdoor soil, the component of indoor dust Pb other than that derived from Pb recently in ambient air) were held constant across the different air quality scenarios simulated. Table 4-2 provides estimates for the General Urban Case Study in the 2007 Pb Risk Assessment (U.S. EPA, 2007f). The General Urban Case Study, unlike the various location-specific case studies, was not based on any specific urban location and reflected several simplifying assumptions including uniform ambient air Pb levels across the simulated, hypothetical study area and a uniform study population.

Table 4-2 Predicted concurrent blood Pb levels and source contributions for children in their seventh year of life.

Air Pb[a] (μg/m^3)	Median Blood Pb[b] (μg/dL)	Pathway Contribution (%)				
		Ingestion				Inhalation
				Indoor Dust		
		Diet[c]	Outdoor Soil/Dust	Other[d]	Pb recently in air[e]	Ambient Air
0.05	1.7 (5.7)[f]	32	44	11	12.6	0.1
0.14[g]	1.9 (6.5)	28	38	6	28.3	0.5
0.2	2.0 (6.9)	26	36	5	32.7	0.7
0.87[h]	2.1 (7.2)	25	33	4	37.2	0.9

[a]Concentrations are maximum calendar quarter averages of Pb in TSP with exception of 0.05 μg/m^3 which is a maximum monthly average

[b]Average of blood Pb concentrations at 75 and 81 months, assuming exposure concentrations were constant through 7 years of life

[c]Includes food and drinking water

[d]Includes indoor dust with Pb contributions from sources other than Pb recently in the air (e.g., indoor paint, outdoor soil/dust, and additional sources including historical air Pb)

[e]Includes contributions associated with outdoor ambient air Pb from ingestion of indoor dust predicted to be associated with outdoor ambient Pb levels

[f]Values in parentheses are the 95th percentile blood Pb for a geometric standard deviation of 2.1

4.1.2 Environmental Exposure Assessment Methodologies

A number of monitoring and modeling techniques have been employed for exposure assessment. These are detailed in either the 2006 Pb AQCD (U.S. EPA, 2006b) or in the subsequent Risk and Exposure Assessment performed as part of the same NAAQS review (U.S. EPA, 2007g). Some of these methods are briefly described here to provide a context for the exposure studies described in Section 4.1.3. Blood Pb sampling is described in detail in Section 4.3.2.

Data collection to assess Pb exposure pathways may involve air, soil, and dust samples. Methods used for digesting air Pb samples are described in Section 3.4, as are ambient air Pb monitoring techniques. Factors affecting collection of ambient air Pb samples are described in detail in Section 3.4. For the monitors in the FRM network, the primary role is compliance assessment. Accordingly, this network includes monitors in locations near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the Pb NAAQS. In such locations, Pb may be

associated with relatively larger size particles, contributing to air Pb concentration gradients with distance from the source and greater deposition in the near-source locations. The FRM network also includes non-source-oriented monitors for which the main objective is to gather information on neighborhood-scale Pb concentrations that are typical in urban areas so to better understand ambient air-related Pb exposures for populations in these areas. This part of the Pb NAAQS network, was required to be operational as of December 27, 2011. These monitor locations are distributed across a broad geographic area, representing approximately 63 large urban areas which contain approximately half of the total U.S. population (based on recently published 2010 Census Bureau data). In lieu of more detailed analysis of population proximity for these newly established monitors, population counts were calculated near previously existing monitors for which data are presented in Section 3.5. For the monitors in that limited dataset, among the total population of 311,127,619 people in the 2010 Census (ESRI, 2011), 181,100 (0.06%) lived within 1 km of a source-oriented monitor, while 918,351 (0.30%) lived within 1 km of a non-source-oriented monitor.

Dust sampling has not changed drastically since it was first proposed by Sayre et al. (1974), in which a disposable paper towel was soaked in 20% denatured alcohol and 1:750 benzalkonium chloride and then used to wipe a 1 ft^2 sampling area in a systematic fashion. Que Hee et al. (1985) and Sterling et al. (1999) compared wipe testing with vacuum methods. Sampling efficiency for the first attempt varied between 53-76% with vacuum pump flow rate and tube type and was 52% for the wipe method for the Que Hee et al. (1985) study, with 100% efficiency after five consecutive samples were obtained. Sterling et al. (1999) observed that two of three vacuuming methods had significantly higher geometric mean collection (vacuum 1: 94.3 µg/ft^2; vacuum 2: 23.5 µg/ft^2) compared with dust wipes (5.6 µg/ft^2).

Models may also be used in exposure assessment. For example, two dispersion models, the American Meteorological Society/Environmental Protection Agency Regulatory Model (AERMOD), and Industrial Source Complex-Plume Rise Model Enhancements (ISC-PRIME) were employed to model dispersion of Pb emissions from specific industrial facilities (Cimorelli et al., 2005; Perry et al., 2005; EPRI, 1997), and to estimate ambient air Pb concentrations at some of the case studies included in the 2007 Risk and Exposure Assessment (U.S. EPA, 2007g). These models assume plume dispersion follows a Gaussian distribution from a point source. For the two point source case studies included in the 2007 risk assessment, the plume models were used to track emissions to ambient air near homes located within a few miles of emitting facilities. However, dispersion models can also be used to track long distance transport of Pb emissions, as performed by Krell and Roeckner (1988) to model the dispersion and deposition of Pb and Cd from European nations into the North Sea.

Several models estimate blood Pb levels resulting from estimated exposure to Pb in environmental media. These models, which are described in detail in the 2006 Pb AQCD (U.S. EPA, 2006b) include the IEUBK model, and the EPA *All Ages Lead Model* (AALM), which combines and expands the thorough exposure and absorption modules of the IEUBK model with the comprehensive biokinetic model of Leggett (1993). As of the writing of this assessment, the AALM is still in development.

The Stochastic Human Exposure and Dose (SHEDS) and NORMTOX models also are capable of modeling metals exposures through various routes including inhalation, ingestion, and dermal exposure (Loos et al., 2010; Burke et al., 2002). Pb exposure modeling can also be accomplished using the Modeling Environment for Total Risk (MENTOR) framework, in which airborne Pb levels could be modeled using AQS, dispersion modeling, or chemical transport modeling, while human exposure is modeled with SHEDS or a similar exposure model (Georgopoulos and Lioy, 2006). Additionally, housing data and time-activity data from the Consolidated Human Activity Database (CHAD) are incorporated into MENTOR to develop refined estimates of Pb exposure and tissue burden. However, a literature search did not produce any Pb exposure studies using the SHEDS, NORMTOX, or MENTOR modeling systems. In general, these models take input for several environmental Pb exposure media including soil, dust, food and water, outdoor air, and indoor air. The models are designed to evaluate different exposure scenarios based on specification of particular conditions.

4.1.3 Exposure Studies

4.1.3.1 Airborne Pb Exposure

Limited personal exposure monitoring data for airborne Pb were available for the 2006 Pb AQCD (U.S. EPA, 2006b). As described above, the NHEXAS study showed personal air Pb concentrations to be significantly higher than indoor or outdoor air Pb concentrations (Clayton et al., 1999). Indoor air Pb concentration was moderately correlated with floor dust and residential yard soil Pb concentration (Rabinowitz et al., 1985). Egeghy et al. (2005) performed multivariate fixed effects analysis of the NHEXAS-Maryland data and found that Pb levels measured in indoor air were significantly associated with log-transformed outdoor air Pb levels, ambient temperature, number of hours in which windows were open, whether homes were built before 1950, and frequency of fireplace usage (Table 4-3).

Table 4-3 Estimates of fixed effects multivariate modeling of Pb levels measured during the NHEXAS-MD study.

	Pb in Indoor Air		Pb in Dust		Dermal Pb		Blood Pb	
Fixed Effect	**β[a]**	**p-value**	**β[a]**	**p-value**	**β[a]**	**p-value**	**β[a]**	**p-value**
Intercept	-0.50	0.0051	6.22	<0.0001	6.23	<0.0001	0.02	0.91

Some recent studies have shown that the ratio of indoor to outdoor Pb-PM varies from site to site depending on factors including infiltration, indoor and outdoor Pb sources, and meteorology. Adgate et al. (2007) measured the concentrations of several trace elements in personal, indoor, and outdoor air samples of $PM_{2.5}$ and found that average personal Pb-$PM_{2.5}$ concentration was roughly three times higher than outdoor air Pb-$PM_{2.5}$ concentration and two times higher than indoor Pb-$PM_{2.5}$ concentration (Table 4-4). Another study of indoor and outdoor air concentrations of Pb was carried out by Molnar et al. (2007). $PM_{2.5}$ trace element concentrations were determined in homes, preschools and schools in Stockholm, Sweden. In all sampled locations, Pb-$PM_{2.5}$ concentrations were higher in the outdoor environment than in the proximal indoor environment. The indoor/outdoor ratios for Pb-$PM_{2.5}$ suggest an outdoor Pb-$PM_{2.5}$ net infiltration of ~0.6 for these buildings. Outdoor air Pb concentrations did not differ between the central and more rural locations. Indoor air Pb concentrations were higher in spring than in winter, which the authors attributed to greater resuspension of elements that had accumulated in road dust over the winter period and increased roadwear on days with dry surfaces. Pekey et al. (2010) measured indoor and outdoor trace element composition of $PM_{2.5}$ and PM_{10} in Kocaeli, an industrial region of Turkey, and found that average airborne Pb concentrations were higher outdoors than indoors for both $PM_{2.5}$ and PM_{10} during summer and for PM_{10} during winter, but that indoor Pb concentration was higher than outdoor Pb concentration for $PM_{2.5}$ during winter. The indoor-to-outdoor ratio of airborne Pb varied by environment; it tended to be less than one, but the ratio varied from one microenvironment to another. In a pilot study in Windsor, Ontario, Rasmussen et al. (2007) observed that the concentration of Pb in $PM_{2.5}$ from a personal exposure sample was roughly 40% higher than the concentration of Pb in outdoor $PM_{2.5}$ and 150% higher than Pb in indoor $PM_{2.5}$. The three studies that included personal samples recorded measurements that were consistently higher than indoor or outdoor levels, and outdoor concentrations were higher than indoor concentrations.

Domestic wood burning is a potential source of Pb compounds (Section 3.2.2.5). Alves et al. (2011) measured trace metals in woodstove and fireplace emissions and found that $PM_{2.5}$ contained Pb, with concentrations from wood burning ranging from 3.3-12.2 µg/g and 2.89-30.3 for woodstoves and fireplaces, respectively. When burning briquettes, the $PM_{2.5}$ measurements showed Pb enrichment above all other metal elements other than potassium (woodstove: 1361 µg/g; fireplace: 616 µg/g). Molnar et al. (2005) measured trace element concentration in indoor and personal exposure $PM_{2.5}$ samples for homes in which wood is burned and in a reference group where no wood burning occurs in the home. For both indoor and personal samples, Molnar et al. (2005) observed that Pb concentrations were higher for the wood burning group and nearly statistically significant for the personal exposure samples (indoor concentration: 6.0 µg/m^3 versus 4.3 µg/m^3, $p = 0.26$; personal exposure: 4.6 µg/m^3 versus 3.0 µg/m^3, $p = 0.06$).

Indoor activity has been associated with resuspension of settled dust, which could cause airborne contact with particle-bound Pb. Qian et al. (2008) estimated a PM_{10} resuspension rate of $1.4x10^{-4}$/hr for one person walking across a carpeted floor. Measurements of submicron particles illustrated a roughly two-fold increase of airborne particle concentration for particles smaller than 1.8 µm for activity versus low activity periods, with maximum concentrations reaching 4-11 times the maximum value during low activity periods. For PM_{10}, average concentration was 2.5 times higher than background levels during activity periods, while peak concentration was 4.5 times higher. Qian and Ferro (2008) observed that resuspension rates depend on particle size, floor material, and ventilation position. Increases in walking speed and weight of the walker did not consistently produce increases in resuspension. 5-10 µm particles produced a higher resuspension rate compared with smaller particles. Newly carpeted areas produced significantly higher resuspension rates than vinyl floors. Zhang et al. (2008) modeled and conducted experiments of particle dispersion from walking and observed that human activity did affect resuspension. They found that larger particles were more readily detached from the carpet by walking motion, but that smaller particles are more easily resuspended once detached. Hunt and Johnson (2012) studied the duration and spatial extent of resuspension of 0.3-5.0 µm particles following walking by a soiled shoe. 0.3-0.5 µm particle concentration remained increased over a time period of 23 min, while 1-5 µm particles declined in concentration over the same time period. Experiments and computational fluid dynamics simulations by Eisner et al. (2010) for a mechanical foot moving on carpeting suggested that the rotating motion of the moving foot on the carpet induced rotating air movement beneath the foot that re-entrained the particles.

Several of the studies can be used to develop an understanding of how personal exposure to PM-bound Pb varies with other exposures. Molnar et al. (2007) reported Spearman correlations of Pb with $PM_{2.5}$ and NO_2 in three outdoor microenvironments (residence, school, and preschool) and found that Pb and other trace metals were generally well correlated with $PM_{2.5}$ ($r = 0.72-0.85$), but Pb was only statistically significantly correlated with NO_2 in one of the three outdoor microenvironments ($r = 0.24-0.75$). Pb was attributed by Molnar et al. (2007) to long range transport. Table 3-29 illustrates that Pb concentrations in the four studies (summarized in the Chapter 3 Appendix [Section 3.8]) are typically well below the level of the NAAQS. The higher personal air concentratoins occurred in a heavily industrialized area of Kocaeli, Turkey with an incinerator and several industrial facilities including metal processing, cement, petroleum refining, and agriculture processing. Otherwise, concentrations were all between 0.002 and 0.006 $\mu g/m^3$. The proportion of Pb compared with other trace metals varied with location and component. It was typically several times lower than S as well as crustal elements such as Ca^{2+} and Fe. In the industrial area of Kocaeli, Pb comprised a greater proportion of the PM compared with other areas.

Table 4-4 Comparison of personal, indoor, and outdoor Pb-PM measurements from several studies.

Study	Location	Pb Metric	Sampling Period	Personal Pb	Indoor Pb	Outdoor Pb
Clayton et al. (1999)	IL, IN, MI, MN, OH, WI	Med. Pb-PM_{50} (ng/m^3)	July, 1995-May, 1997	13	6.6	8.5

4.1.3.2 Exposure to Pb in Soil and Dust

The 2006 Pb AQCD (U.S. EPA, 2006b) lists indoor Pb dust infiltrated from outdoors as a potential source of exposure to Pb soil and dust. Thus, outdoor soil Pb may present an inhalation exposure if resuspended indoors or an ingestion exposure during hand-to-mouth contact. A detailed description of studies of outdoor soil Pb concentration is provided in Section 3.6.1. Indoor measurements can reflect infiltrated Pb as well as Pb dust derived from debrided paint, consumer products, or soil that has been transported into the home via foot traffic. Table 4-5 presents indoor dust Pb concentrations for 2006-2011 observational studies in which indoor dust Pb was measured.

Table 4-5 Measurements of indoor dust Pb concentration from 2006-2011 studies.

Reference	Study Location	Metric (units)	Sample Site	Indoor Pb Concentration
Caravanos et al. (2006b)	New York City, New York	Weekly dust loading (μg/m^2)	Glass plate next to open window of academic building	Median: 52
Khoder et al. (2010)	Giza, Egypt (extensive leaded gasoline use; industrial area)	Weekly dust loading (μg/m^2)	Glass plate in second-floor living room of apartments	Median: 408
Brattin and Griffin (2011)	Eureka, Utah near Eureka Mills Superfund Site	Dust concentration (mg/kg)	Indoor home site (not specified)	160-2000
	Denver, CO, near VBI70 Superfund Site		Indoor home site (not specified)	11-660
	East Helena, MT, near East Helena Superfund Site		Indoor home site (not specified)	68-1000
Yu et al. (2006)	Syracuse, New York	Dust concentration range (mg/kg)	Floor	Range: 209-1770
Turner and Simmonds (2006)	Birmingham, Plymouth, and 2 rural sites, U.K.	Dust concentration (mg/kg)	Floor	Median: 178
Gaitens et al. (2009)	U.S. (nationwide)	Dust loading (μg/m^2)	Smooth floor	Median: 1.7 Avg.: 4.4
			Rough floor	Median: 5.6 Avg.: 16
			Smooth windowsill	Median: 2.5 Avg.: 190
			Rough windowsill	Median: 55 Avg.: 480
Wilson et al. (2007)	Milwaukee, Wisconsin	Dust concentration (μg/m^2)	Central perimeter	Avg.: 107
			Entry	Avg.: 140
			Window	Avg.: 151
Zota et al. (2011)	Ottawa County, Oklahoma (area surrounding the Tar Creek Superfund Site)	Dust concentration (mg/kg)	Indoor (site not specified)	Avg.: 109 Median: 63 Max.: 881
Spalinger et al. (2007)	Rural towns, Idaho	Dust concentration (mg/kg)	Vacuum	Median: 120 Max: 830
			Floor	Median: 95 Max: 1,300
	Bunker Hill, Idaho Superfund site	Dust concentration (mg/kg)	Vacuum	Median: 470 Max: 2,000
			Floor	Median: 290 Max: 4,600

Several studies suggested the infiltration of Pb dust into buildings. For example, Caravanos et al. (2006b) collected dust on glass plates at an interior location near an open window, a sheltered exterior location, and an open exterior location for a two-year period in Manhattan, NY. Median weekly dust loading was reported to be 52 μg/m^2 for the indoor site, 153 μg/m^2 for the unsheltered outdoor site, and 347 μg/m^2 for the sheltered outdoor site. This paper demonstrated the likely role of outdoor Pb in influencing indoor dust Pb loading and indicated that under quiescent conditions (e.g., no cleaning) near an open second-story window, the indoor dust Pb level might exceed EPA's hazard level for interior floor dust of 430 μg/m^2 (40 μg/ft^2). Khoder et al. (2010) used the same methodology to study Pb dust deposition in residential households in the town of Giza, Egypt, located between two industrial areas and where leaded gasoline is still in use; the investigators reported a median weekly deposition rate of 408 μg/m^2 and an exterior median deposition rate of 2,600 μg/m^2. In the latter study, Pb deposition rate correlated with total dust deposition rate (R=0.92), Cd deposition rate (R=0.95), and Ni deposition rate (R=0.90). Statistically significant differences in Pb deposition rates were observed between old and new homes ($p < 0.01$) in the Khoder et al. (2010) study, although the only quantitative information provided regarding home age stated that the oldest home was 22 years old when the study was performed in 2007. Khoder et al. (2010) found no statistically significant difference between Pb loadings when segregating the data by proximity to roadways. Recently, Brattin and Griffin (2011) performed linear regressions of dust Pb on soil Pb based on data collected previously for outdoor soil Pb and indoor dust Pb near mining and/or smelting Superfund sites in Utah, Colorado, and Montana (U.S. EPA, 2005f; SRC, 2002; U.S. EPA, 2001). They observed that the dust Pb concentration was 4-35% of outdoor soil Pb. Excluding outliers on the regression, dust Pb concentration ranged from 160-2,000 mg/kg, 11-660 mg/kg, and 68-1,000 mg/kg at three sites.

Correlations between indoor and outdoor Pb content in dust can be partially explained with speciation. Beauchemin et al. (2011) used XANES to speciate in-home paint samples to assess the contributions of indoor paint and outdoor material to indoor dust Pb concentrations. In indoor dust samples of particles <150 μm in size, Pb oxide, Pb sulfate, and Pb carbonate were measured. These materials commonly were used in white paint. In the size fraction of particles <36 μm, half of the measured Pb was associated with Fe-oxyhydroxides such as ferrihydrite and goethite and presumably adsorbed onto these species. This finding suggested that a mix of indoor and outdoor sources may affect the composition of dust in the smaller size fraction in houses with leaded paint.

Residual Pb dust contamination following cleaning activities has been documented. For instance, Hunt et al. (2008) estimated Pb deposition and concentration from experiments in which Herculaneum, MO yard soil samples that had been dried, ground, and sieved

were tracked onto a tile test surface and then repeatedly cleaned until visual inspection of the tiles uncovered no surface discoloration. Cleaning resulted in a 5-6 fold decrease in residual Pb, with 7,100 µg/m^2 measured after multiple walks across the sample floor prior to cleaning. Yu et al. (2006) analyzed dust samples from 50 homes in northern New Jersey (typically of older housing stock, although the study does not specify housing age). The investigators found that total Pb concentration in carpet dust ranged from 209 to 1,770 mg/kg dust. Wilson et al. (2007) studied Pb dust samples from homes in Milwaukee, WI, and in resident children with and without elevated blood Pb ≥ 10 µg/dL. They found that Pb dust samples obtained from the floor were always significantly higher in residences of children with elevated blood Pb, with the exception of samples from the bathroom floor. Windowsill dust was not significantly higher in residences of children with elevated blood Pb. Residual Pb dust in homes is a potential exposure source for small children who use touch to explore their environments.

Pb dust on floors, windowsills, and other accessible surfaces is related to several demographic, socioeconomic, and housing conditions. Gaitens et al. (2009) used National Health and Nutrition Examination Survey (NHANES) data from 1999 through 2004 to examine Pb in dust in homes of children ages 12-60 months. Floor Pb dust loading value was modeled against several survey covariates and was significantly associated with several covariates but with mixed sign ($p < 0.05$). Floor Pb dust was positively associated with windowsill Pb dust loading, being of non-Hispanic black race/ethnicity, and presence of smokers in the home. Floor Pb dust was negatively associated with presence of carpeting, poverty-to-income ratio, and living in a home built after 1950. It was nearly significantly and positively associated ($p = 0.056$) with renovations made to pre-1950 homes. Windowsill Pb dust level was also significantly associated ($p < 0.05$) with several covariates. It was positively associated with being of non-Hispanic black race/ethnicity, negatively associated with living in a home built after 1950, positively associated with not smooth and cleanable window surface condition, positively associated with presence of smokers in the home, and positively associated with deterioration of indoor paint. It was nearly statistically significantly and positively associated ($p = 0.076$) with deterioration of outdoor paint when homes were built prior to 1950. Dust Pb loading was found by Egeghy et al. (2005) to be significantly and positively associated with the log-transform of soil Pb concentration, cement content in the home entryway, frequency of fireplace usage, and homes built before 1950. Dust Pb loading was significantly and negatively associated with indoor pesticide use and number of hours in which windows were open (Table 4-3).

Building demolition and renovation activities can create dust from interior and exterior paints with Pb content. Mielke and Gonzales (2008) measured Pb content in paint chips from paint applied prior to 1992 and found that median Pb levels were 420 mg/kg for

interior paint and 77,000 mg/kg for exterior paint. Maximum levels were 63,000 mg/kg and 120,000 mg/kg for interior and exterior paint, respectively. Mielke et al. (2001) compared dust samples from two New Orleans houses that were prepared for painting. One home was power sanded without any confinement or control of removed material, while the other was hand-scraped with containment and collection of paint chips. Immediately after sanding, Pb dust samples ranged from <3 to 28,000 mg/kg at the sanded house. Pb dust samples from the scraped house ranged from 7 to 1,200 mg/kg.

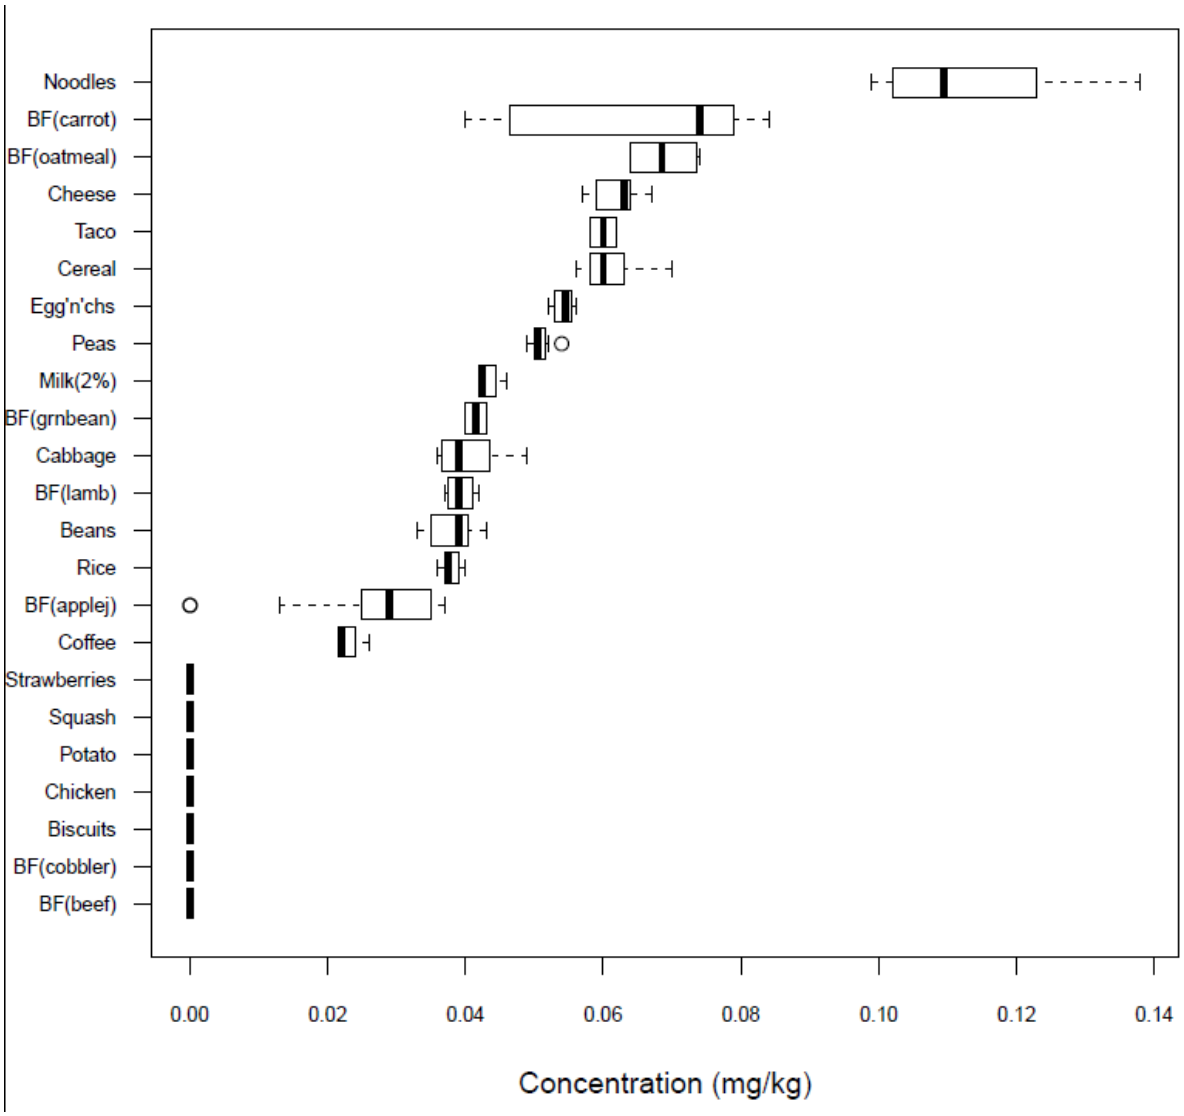
Dust Pb concentrations have also been reported for homes in the vicinity of historic and active metals mining and smelting sources. As described in Section 3.6.1, soil Pb has been found to be elevated near source of ambient air Pb. Near an active smelter in Port Pirie, Australia, median hand dust Pb loadings increased with age among a cohort of fourteen children followed over age 0-36 months (2-5 months: 54 $\mu g/m^2$, >15 months: 336 $\mu g/m^2$) (Simon et al., 2007). Zota et al. (2011) studied Pb dust and indoor Pb-$PM_{2.5}$ concentration in Ottawa County, OK near the Tar Creek Superfund Site, in which a metals mine had closed. Statistically significant correlations among outdoor soil Pb concentration, indoor dust Pb concentration, indoor dust Pb loading, and indoor air Pb-$PM_{2.5}$ concentrations were observed (r = 0.25-0.65), with an average dust Pb concentration of 109 mg/kg, dust Pb loading of 54 $\mu g/m^2$, soil Pb concentration of 201 mg/kg, and indoor Pb-$PM_{2.5}$ concentration of 1 ng/m^3. House dust Pb concentrations were found to increase significantly with residential proximity to two chat (i.e., dry mining waste) sources and to decrease with distance to the street and presence of central air conditioning. Spalinger et al. (2007) measured Pb in dust in homes in a 34 km^2 area surrounding a designated Superfund site where a Pb and Zn smelter formerly operated at Bunker Hill, ID. During spring of 1999, vacuum and floor mat samples were taken from homes in three towns within the 34 km^2 area and five “background” towns further from the Superfund site. For the background towns, Pb concentration in vacuum dust had a median of 120 mg/kg, and Pb concentration in floor dust had a median of 95 mg/kg. The median Pb dust loading rate was measured to be 40 $\mu g/m^2$ per day. In contrast, Pb in vacuum dust and floor mats for the towns contained within the Bunker Hill Superfund site had a median Pb concentration of 470 mg/kg and 290 mg/kg, respectively. The median Pb loading rate for indoor dust in houses in these towns was 300 $\mu g/m^2$ per day. These results suggest that those living in close proximity to large Pb and Zn smelters or mines that are now Superfund sites are at much greater risk of exposure to Pb dust compared to the general population.

Pb exposure has been reported on children’s playgrounds. Mielke et al. (2011a) reported median soil Pb concentration of 558 mg/kg on playground soils at eleven New Orleans daycare or community centers. Following remediation efforts to cover playground soil with clean soil, median concentration dropped to 4.1 mg/kg. Duggan et al. (1985)

reported on the concentration and size distribution of wipe samples on the hands of 368 pre-school children from eleven schools in London, U.K.. Hand Pb residue (PbH) values were modeled as linear ($p < 0.05$) and power functions ($p < 0.001$) of Pb dust; linear slope was 0.0064 µg hand Pb residue per mg/kg Pb dust. Given that the Duggan et al. (1985) study was performed when Pb additives were used in gasoline, dust Pb concentration values are not reported here. As described in Section 4.1.1.1, exposure to Pb in soil and dust may be related to size distribution of the soil or dust particles, with higher Pb enrichment in the smaller particles.

4.1.3.3 Dietary Pb Exposure

This subsection covers several dietary Pb exposures from a diverse set of sources. Included among those are drinking water, fish and meat, agriculture, urban gardening, dietary supplements, tobacco, cultural food sources, and breastfeeding. The breadth of dietary Pb exposures is illustrated in Figure 4-2, which illustrates the data obtained in the 2008 FDA Total Diet Study market basket survey (FDA, 2008). Among the highest Pb concentrations were those for noodles, baby food carrots, baby food oatmeal, Swiss cheese, beef tacos from a Mexican restaurant, and fruit-flavored cereal. Possible sources of Pb in food samples include introduction during processing or preparation with drinking water contaminated with Pb, deposition of Pb onto raw materials for each food, and Pb exposure in livestock that produce dairy or meat ingredients. Manton et al. (2005) used Pb isotope ratios to estimate sources of dietary Pb among a cohort of mothers and children from Omaha, NE using a combination of food samples, hand wipes, house dust wipes, and aerosol samples collected between 1990 and 1997. Drinking water Pb was not included in this study. The authors cited results from Egan et al. (2002) that imported vegetables contributed 55% of Pb dietary intake for infants, 30% for 2-6 year old children, and 20% for 25-30 year old women. Imported candy contributed 10% of Pb dietary intake for 2-6 year old children and 9% for 25-30 year old women. Isotopic data from Manton et al. (2005) suggested that, with the exception of children age 0-12 mos, house dust is a large contributor to dietary Pb. The pattern of certain Pb-isotope ratios observed in the diet of children 0-12 mos are suggested to derive from Ca salts in limestone that may have been used in dietary supplements in baby formula. The contribution of ambient Pb aerosols to dietary Pb samples was not statistically significant for this urban exposure study.



Note: from the 2008 FDA Total Diet Study. "BF" denotes baby food.

Figure 4-2 Market basket survey results for Pb concentration in foods.

Drinking Water

Pb concentrations in drinking water vary substantially. For example, Shotyk and Krachler (2009) measured the Pb concentration in tap water, commercially bottled tap water and bottled natural water. They found that, in many cases, tap water contained less Pb than bottled water. Excluding bottled water in glass containers because Pb can be leached from the glass, the median Pb concentration in the bottled water samples was 8.5 ng/L (range $\leq$ 1 to 761 ng/L). Pb in drinking water supplies can derive from atmospheric deposition onto surface waters, runoff of atmospheric deposition as described in Section 3.3, or via corrosion of Pb in the distribution network exacerbated by contact with acidic disinfection byproducts, as described in the following paragraphs.

It is now recognized that environmental nanoparticles (NPs) (~1-100 nm) can play a key role in determining the chemical characteristics of treated drinking water as well as natural waters (Wigginton et al., 2007). An important question is whether or not NPs from source waters affect the quality of drinking water. For example, if Fe-oxide NPs are not removed during the flocculation/coagulation stage of the treatment process, they may become effective transporters of contaminants such as Pb, particularly if these contaminants are leached from piping in the distribution system.

Corrosion byproducts can influence Pb concentrations in drinking water. Schock et al. (2008) characterized Pb pipe scales from 91 pipes made available from 26 different municipal water systems from across the northern U.S. They found a wide range of elements including Cu, Zn and V as well as Al, Fe and Mn. Interestingly, V was present at nearly one percent levels in pipes from many geographically diverse systems. In a separate study, Gerke et al. (2009) identified the corrosion product, vanadinite ($Pb_5(VO_4)_3Cl$) in Pb pipe corrosion byproducts collected from 15 Pb or Pb-lined pipes representing 8 different municipal drinking water distribution systems in the Northeastern and Midwest regions of the U.S. Vanadinite was most frequently found in the surface layers of the corrosion products. The vanadate ion, VO_4^{3-}, essentially replaces the phosphate ion in pyromorphite and hydroxyapatite structures. It is not known whether the application of orthophosphate as a corrosion inhibitor would destabilize vanadinite, but this substitution would have implications for V release into drinking water. The stability of vanadinite in the presence of monochloramine is also not known, and its stability might have implications for both Pb and V release into drinking water.

In recent years, drinking water treatment plants in many municipalities have switched from using chlorine to other disinfecting agents because their disinfection byproducts may be less carcinogenic. However, chloramines are more acidic than chlorine and can increase Pb solubility (Raab et al., 1991) and increase Pb concentrations in tap water. For example, after observing elevated Pb concentrations in drinking water samples, Kim and

Herrera (2010) observed Pb oxide corrosion scales occurring after using acidic alum as a disinfection agent. Edwards and Dudi (2004) observed a red-brown particle-bound Pb in Washington, D.C. water that could be confused with innocuous Fe. The source of the particle-bound Pb was not known but was thought to originate from the source water. The high Pb concentrations were attributed to leaching of Pb from Pb-bearing pipes promoted by breakdown products of disinfection agents (Edwards and Dudi, 2004). Maas et al. (2007) tested the effect of fluoridation and chlorine-based (chlorine and chloramines) disinfection agents on Pb leaching from plumbing soldered with Pb. When using chlorine disinfection agents alone, the Pb concentration in water samples doubled during the first week of application (from 100 to 200 ppb) but then decreased over time. When adding fluorosilicic acid and ammonia, the Pb concentration spiked to 900 ppb and increased further over time. However, Macek et al. (2006) regressed blood Pb among children ages 1-16 years on fluoride treatment, adjusted for several demographic and socioeconomic factors, and found no association when all data were combined into one model; when stratifying by housing age, Macek et al. (2006) found statistically significant odds ratios for those living in housing built before 1946 or for housing age unknown. Similarly, Lasheen et al. (2008) observed Pb leaching from pipes in Egypt when exposed to an acid of pH = 6. Exposure to basic solutions actually resulted in reduction of Pb concentration in the drinking water. Leaching of Pb from pipes following disinfection with acidic agents can lead to increased Pb exposure; Miranda et al. (2007b) observed a statistically significant association between blood Pb levels among children living in Wayne County, NC and use of chloramines ($p < 0.001$) in a log-linear model, although the study did not control for the presence of Pb paint in the dwellings, so it is difficult to distinguish the influence of Pb pipes from Pb in paint on blood Pb levels.

Several chemical mechanisms may contribute to release of Pb during use of chloramine disinfection agents. Edwards and Dudi (2004) hypothesized that Pb leaching occurs when chloramines cause the breakdown of brass alloys and solder containing Pb. After observing that nitrification also leads to increased Pb concentrations in water, they also proposed that chloramines may trigger nitrification and hence cause decreasing pH, alkalinity, and dissolved oxygen that leads to corrosion after observing that nitrification also leads to increased Pb concentrations in water. However, Zhang et al. (2009b) found no evidence that nitrification brought about significant leaching of Pb from Pb pipes. Lytle et al. (2009) suggested that a lack of increased Pb(II) concentrations in drinking water following a change from free chlorine to chloramine disinfection is attributed to the formation of the Pb(II) mineral hydroxypyromorphite ($Pb_5(PO_4)_3OH$) instead of Pb(IV) oxide. Xie et al. (2010) further investigated the mechanisms by which Pb(II) release is affected by chloramines. Two opposing mechanisms were proposed: $Pb(IV)O_2$ reduction by an intermediate species from decomposition of monochloramine; and increasing redox potential which decreases the thermodynamic driving force for reduction. They suggest

that the contact time of monochloramine with PbO_2 and the Cl_2:N ratio in monochloramine formation will determine which mechanism is more important. Free chlorine can control Pb concentrations from dissolution under flowing conditions but for long stagnation periods, Pb concentrations can exceed the action level: 4-10 days were required for Pb concentrations to exceed 15 µg/L (for relatively high loadings of PbO_2 of 1 g/L). Thus, under less extreme conditions, it was concluded that chloramination was unlikely to have a major effect on the release of Pb into drinking water.

Agriculture

The 2006 Pb AQCD (2006b) states that surface deposition "represents a significant contribution to the total Pb in and on the plant", while uptake through a plant's roots can also contribute to a plant's Pb concentration. Consequently, Pb content in plants may contribute to human dietary exposure. Uptake of Pb by plants growing in contaminated soil has been repeatedly demonstrated in some species during controlled potted plant experiments (Del Río-Celestino et al., 2006). In this study, most species retained Pb in the roots with little mobilization to the shoots of the plants. However, certain species of grasses were able to mobilize Pb from the roots to the shoots of the plant; these specific species could lead to human exposures through consumption of grazing animals. Lima et al. (2009) conducted similar greenhouse experiments with several vegetable crops grown in soil contaminated by Pb-containing residue from battery recycling waste. In this study, carrots had high bioaccumulation, measured as the percent of Pb concentration measured in the plant compared with the Pb concentration in the soil, with little translocation of the Pb to the shoots. Conversely, beets, cabbages, sweet peppers, and collard greens had low bioaccumulation but moderate to high translocation. Okra, tomatoes, and eggplants had moderate bioaccumulation and moderate to high translocation. Sesli et al. (2008) also noted uptake of Pb within wild mushrooms. Vandenhove et al. (2009) reviewed bioaccumulation data for plant groupings and found that grasses had the highest uptake, followed by leafy vegetables and root crops grown in sandy soils; see Table 4-6. These references also suggested high transfer from roots to shoots among root crops, with shoots having roughly four times higher Pb bioaccumulation than roots.

Sources of atmospheric Pb can lead to vegetable contamination. For example, Uzu et al. (2010) found that Pb deposition from smelter emissions caused a linear increase in Pb concentrations of 7.0 mg/kg per day (R^2=0.96) in lettuce plants cultivated in the courtyard of a smelter. They reported that lettuce grown 250-400 meters from the smelter had concentrations that were 10-20 times lower, which is consistent with findings described in Section 3.3 that deposition of Pb containing material drops off with distance from a source. Pb contamination of crops may also occur through piston-engine aircraft Pb emissions during aerial application of fertilizers and pesticides. In 2010, the U.S.

Federal Aviation Administration (FAA) recorded 396,000 hours of flight time for aerial application. This term encompasses crop and timber production including seeding cropland and fertilizer and pesticide application. It is estimated that 86% of these flight-hours involved piston engine aircraft utilizing leaded fuel (FAA, 2010).

Some land use and soil characteristics have been shown to increase bioaccessibility of Pb in soil, which could then lead to plant contamination. Fernandez et al. (2010; 2008; 2007) measured Pb from atmospheric deposition in two adjacent plots of land having the same soil composition but different uses: one was pasture land and one was agricultural. In the arable land, size distributions of soil particle-bound Pb, were uniformly distributed. In pasture land, size distributions of soil particle-bound Pb were bimodal with peaks around 2-20 μm and 50-100 μm (Fernandez et al., 2010). For the agricultural plot, Pb concentration was constant around 70 mg/kg in samples taken over the first 30 cm of soil, at which time it dropped below 10 mg/kg at soil depths between 35 and 100 cm. In contrast, Pb concentration in pasture land peaked at a depth of 10 cm at a concentration of roughly 70 mg/kg and then dropped off gradually to approach zero concentration at a depth of approximately 50 cm. The sharp change in concentration for the arable land was attributed to a combination of plowing the soil and use of fertilizers to increase the acidity of the soil and solubility of Pb into the soil (Fernandez et al., 2007). They found that the surface layer was acidic (pH: 3.37-4.09), as was the subsurface layer (pH: 3.65-4.38). Jin et al. (2005) examined how soil characteristics affect Pb contamination of crops by testing soil Pb, bioaccessibility of soil Pb (determined by $CaCl_2$ extraction), and Pb in tea samples from tea gardens. They observed that the Pb concentration in tea leaves was proportional to the bioaccessible Pb in soil.

There is some evidence that Pb contamination of crops can originate with treatment of crops. For example, compost produced from wastewater sludge has the potential to add Pb to crops. Cai et al. (2007) demonstrated that production of compost from sludge enriched the Pb content by 15-43% compared with the Pb content in sludge prior to composting. Chen et al. (2008b) observed that the median concentration of Pb in California crop soil samples was 16.2 mg/kg (range: 6.0-62.2 mg/kg). Chen et al. (2008a) further observed that in three of the seven California agricultural regions sampled, concentrations of Pb increased following addition of fertilizer, but the increase was less than that for phosphorous (P) and Zn indicators of fertilizer. In four regions, there was no increase of Pb at all. Furthermore, Tu et al. (2000) observed a decrease in Pb fraction with increasing P application. Nziguheba and Smolders (2008) also surveyed phosphate-based fertilizers sold in European markets to determine the contribution of these fertilizers to heavy metal concentrations in agricultural products. They reported a median fertilizer Pb concentration of 2.1 mg/kg based on total weight of the fertilizer, with a 95th percentile concentration of 7.5 mg/kg. Across Europe, Nziguheba and Smolders (2008)

estimated that the amount of Pb applied via fertilizers to be only 2.6% of that resulting from atmospheric deposition.

Although Pb in on-road vehicle gasoline has been phased out in the U.S., if imported crops are produced in countries that still use Pb antiknock agents in on-road gasoline, they have the potential to introduce dietary Pb to U.S. consumers. For example, high concentrations of Pb have been found in chocolate from beans grown in Nigeria, during the time when leaded gasoline was still legally sold. Rankin et al. (2005) observed that the ratios of ^{207}Pb to ^{206}Pb and ^{208}Pb to ^{207}Pb were similar to those of Pb in gasoline. Although this study showed that Pb concentration in the shelled cocoa beans was low (~1 ng/g), manufactured cocoa powder and baking chocolate had Pb concentrations similar to those of the cocoa bean shells, on the order of 200 ng/g, and Pb concentration in chocolate products was roughly 50 ng/g (Rankin et al., 2005). It is possible that the increases were attributed to contamination of the cocoa by the shells during storage or manufacture, but the authors note that more research is needed to verify the source of contamination.

Findings from Pb uptake studies have implications for urban gardening if urban soils may be contaminated with Pb. For instance, Clark et al. (2006) tested the soil in 103 urban gardens in two Boston neighborhoods. Using isotopic analysis, they found that Pb-based paint contributed 40-80% of Pb in the urban garden soil samples, with the rest coming from historical gasoline emissions. Furthermore, Clark et al. (2006) estimated that Pb consumption from urban gardens can be equivalent to 10-25% of the exposure to Pb from drinking water for children living in the Boston neighborhoods studied. Because soil Pb levels in urban areas will depend on surrounding sources (Pruvot et al., 2006), Pb exposures in urban garden vegetables will vary.

Table 4-6 Pb bioaccumulation data for various plants. Bioaccumulation is expressed as percent of Pb concentration in the plant to the Pb concentration in the soil.

Plant Group	Plant Compartment	Soil	n	GM	GSD	AM	SD	Min	Max

Game

Atmospheric sources of Pb have also been shown to contaminate game meat, thus potentially posing a risk of Pb exposure. In Pb mining or smelting areas, several studies have documented Pb concentrations in game [e.g., (Nwude et al., 2010; Reglero et al., 2009b)].

Potential Pb exposure through consumption of animals exposed to or killed with Pb shot has also been well documented (Hunt et al., 2009; Tsuji et al., 2009; Tsuji et al., 2008; Hunt et al., 2006). For example, Martínez-Haro et al. (2010) observed Pb in the feces of mallards that ingested gunshot of 34-13,930 mg/kg with a median of 1,104 mg/kg, while mallards that did not ingest gunshot had feces Pb levels <12.5 mg/kg. Mateo et al. (2011) studied Pb bioaccessibility as a function of cooking method for breast meat from partridges killed with gunshot. They observed that preparation in cold or hot vinegar increased bioaccessibility compared with total Pb in the samples.

Fish

Pb content in fish could also lead to human exposure to Pb (U.S. EPA, 2006b, 1986a). Ghosh et al. (2007) demonstrated in laboratory experiments that exposure to Pb in water can lead to linearly increasing Pb levels in the kidneys, liver, gills, skeleton, and muscle of fish. Several studies have documented the potential for human Pb exposure through fish and seafood. Welt et al. (2003) conducted a survey of individuals who fished in Bayou St. John, Louisiana in conjunction with sampling Pb content in sediment. They found that median sediment Pb concentrations ranged from 43 to 330 mg/kg in different locations, while maximum sediment Pb concentrations ranged from 580 to 6,500 mg/kg. In total, 65% of the surveyed individuals fished for food from the Bayou, with 86% consuming fish from the Bayou each week. In a study of the effect of coal mining on levels of metals in fish (measured as blood Pb) in northeastern Oklahoma, Schmitt et al. (2005) found that fish blood Pb levels varied with respect to species of fish, but blood Pb levels were higher in fish in areas close to mining activities. Similarly, Besser et al. (2008) observed higher levels of fish blood Pb close to mining activities in southeastern Missouri. In a related study of fish species in the same region of Missouri, fish blood Pb levels were found to be statistically significantly higher in sites within 10 km downstream of active Pb-Zn mines ($p < 0.01$) compared with fish located further from the mines (Schmitt et al., 2007a), and elevated fish blood Pb levels were again noted near a Pb-Zn mine (Schmitt et al., 2009). It was noted that the Ozark streams where these studies were performed were often used for recreational fishing.

Breast Milk

Studies of breastfeeding women suggest that infants may be exposed to Pb in breast milk. Ettinger et al. (2004a) observed in a 1994-1995 study of Mexico City women that at 1 month postpartum, 88 women breastfeeding exclusively (with mean blood Pb level of 9.4 µg/dL) had breast milk Pb concentrations of 1.4 ± 1.1 µg/L, and 165 women breastfeeding partially (with mean blood Pb level of 9.5 µg/dL) had breast milk Pb concentrations of 1.5 ± 1.2 µg/L. During the same time period, Ettinger et al. (2006) studied breastfeeding women in Mexico City over a child's first year of life and sampled Pb concentration in breast milk at 1, 4, and 7 mo post-partum. They observed that mean breast milk concentrations dropped from 1.4 µg/L at 1 mo (mean maternal blood Pb = 9.3 µg/dL) to a mean of 1.2 µg/L at 4 mo (mean maternal blood Pb = 9.0 µg/dL) to 0.9 µg/L at 7 mo (mean maternal blood Pb = 8.1 µg/dL); this reduction was statistically significant ($p < 0.00001$). Among the 310 women included in the study, 181 had previous pregnancies. In one study of nursing mothers living in Port Pirie, Australia near a Pb smelter, 10 of the 11 mothers had breast milk concentrations <5 µg/L (Simon et al., 2007). The authors hypothesized that breast milk concentration was too low to be a major contributor to blood Pb level in these infants relative to other factors such as hand loading of Pb. However, one mother with a blood Pb level of 25 µg/dL had a breast milk Pb level of 28 µg/L (Simon et al., 2007).

In summary, several sources of dietary Pb can originate from atmospheric Pb emissions, including drinking water, vegetables, game, fish, and breast milk. Drinking water Pb levels are affected by source strength and proximity, runoff, and water treatment processes and chemicals. Among plants grown for agriculture, Pb content is highest in grasses, followed by leafy vegetables, then root vegetables. Pb in soil or dust can also collect on the surfaces of vegetables. Pb contamination of vegetables depends on a number of factors, including presence of nearby sources of atmospheric Pb, soil type and chemistry, land use, and land treatment. Other sources of Pb, such as international consumer products or historic emissions, also have the potential to introduce Pb into the U.S. diet. Pb contamination through the food chain potentially leads to elevated Pb levels in meat. Likewise, Pb contamination of surface waters can lead to elevated levels of Pb in fish used for consumption. Breastfeeding also presents a potential Pb exposure to newborn babies, and that exposure drops off as the mothers nurse and as the babies age and add more food to their diet.

4.1.3.4 Occupational

Occupational environments have the potential to expose individuals to Pb. Some modern day occupational exposures are briefly discussed below in the context of understanding potential exposures that are not attributed to ambient air. For example, Miller et al. (2010) obtained personal and area samples of particle-borne Pb in a precious metals refinery; year of the study was not reported. It was not stated explicitly, but it is likely that Miller et al. (2010) measured the PM as TSP because the Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for Pb is based on TSP rather than a smaller size cut, and the OSHA PEL was used for comparison. Concentrations measured by personal samples ranged from 2 to 6 $\mu g/m^3$, and concentrations from area samples ranged from 4 to 14 $\mu g/m^3$. The OSHA PEL is 5 $\mu g/m^3$. In steel production, sintering was found to be the largest source of airborne Pb exposure in a survey of operations (Sammut et al., 2010), with Pb enrichment in PM reported to be 20,000 mg/kg. Although total PM concentration was not reported by the authors, the PM was reported to have 75% of its particulate mass at below the 2.5 µm diameter size.

Operations involving Pb-containing materials in various industries are a source of occupational Pb exposure, in addition to a residential exposure. Rodrigues et al. (2010) reported exposures to airborne Pb among New England painters, who regularly use electric grinders to prepare surfaces for painting. Two-week averaged airborne Pb concentrations, sampled with an Institute of Medicine inhalable PM sampler designed to capture PM smaller than 100 µm, were reported to be 59 $\mu g/m^3$, with a maximum daily value of 210 $\mu g/m^3$. The Pb concentrations reported here were corrected by the National Institute for Occupational Safety and Health (NIOSH) respirator protection factors, although the respirator protection factors were not reported by Rodrigues et al. (2010). Information on the air Pb-blood Pb relationship can be found in Section 4.5.1.

4.1.3.5 Exposure to Pb from Consumer Products

Pb is present in varying amounts in several consumer products including alternative medicines, candies, cosmetics, pottery, tobacco, toys, and vitamins (Table 4-7). Several of these categories suggest children may incur regular exposures. Pb concentrations were reported to range from non-detectable levels up to 77% by mass, for the case of one medicinal product. Exposure to these products, which originate in a range of different countries, can account for substantial influence on Pb body burden (Miodovnik and Landrigan, 2009; Levin et al., 2008).

Table 4-7 Pb content in various consumer products.

Product Category	Product	Location of Purchase*	Pb Content (units)	Reference
Alternative and Traditional Medicines	*Cissus quadrangularis, Caulophyllum thalictroides, Turnera diffusa, Centella asiatica, Hoodia gordonii, Sutherlandia frutescens, Curcuma longa, fucoxanthin, Euterpe oleracea* (dietary supplements claimed to be from *Hoodia gordonii*)	U.S. (Mississippi)[a]	Not detected (N.D.)[b] to 4.21 mg/kg	Avula et al. (2010)
	Malva sylvestris	Turkey	1.1-2.0 mg/kg	Hiçsömnez et al. (2009)
	Yugmijihwang-tang, Bojungigki-tang, Sibjeondaebo-tang, Kuibi-tang, Ojeogsan	Korea	7.9×10^{-6} to 2.5×10^{-5} mg/kg body weight/day	Kim et al. (2009a)
	Lemongrass, licorice, holy basil, cloves, ginger	India	Average: Lemongrass & Holy Basil Leaves: 6.1 mg/kg; Licorice Stolons: 6.1 mg/kg, Clove Dried Flower Buds: 7.8 mg/kg, Ginger Rhizome: 5.8 mg/kg	Naithani and Kakkar (2006)
	B-Success 28, Operation Sweep, Aloe Vera Plus Bitter Aloes, Zarausmacine, Virgy-Virgy Computer Worm-Expeller, Dorasine Powder, Sexual Energy, U&DEE Infection Cleansing Powder, U&DEE Sweet Bitter, Natural Power Stone, Chama Black Stone, Portugal Antiseptic Soap, Edysol Antiseptic Soap, H-Nal, M-Reg, Veins Flocher, Diabor, C-Candi, C-Cysta, Firas, D-Diab, P-Pile, Infecta, Ribacin Forte, Aloe Vera Cure Formula	Nigeria	925-27,000 µg	Obi et al. (2006)
	Shell of Hen's Egg	India	14 mg/kg	Sharma et al. (2009)
	Berberis (*B. aristata, B. chitria, B. asiatica, B. lyceum*), Daruharidra	India	Berberis: Roots: 3.1-24.7 mg/kg Stems: 8.0-23.8 mg/kg Daruharidra: 16.9-49.8 mg/kg	Srivastava et al. (2006)
	Greta powder	U.S. (California)	770,000 ppm	CDC (2002)
Candy	Tamarind Candy	U.S. (Oklahoma)	Product: 0.15-3.61 mg/kg Stems: 0.36-2.5 mg/kg Wrappers: 459-27,125 mg/kg	Lynch et al. (2000)
	Tamarind Candy	U.S. (California)	Product: 0.2-0.3 mg/kg Stems: 400 mg/kg Wrappers: 16,000-21,000 mg/kg	CDC (2002)
Cosmetics	Lipsticks	U.S.	Average: 1.07 mg/kg	Hepp et al. (2009)
	Eye Shadows	Nigeria	N.D. to 55 mg/kg	Omolaoye et al. (2010a)

Product Category	Product	Location of Purchase*	Pb Content (units)	Reference
Pottery	Foods prepared in Pb-glazed pottery	Mexico	N.D. to 3,100 mg/kg	Villalobos et al. (2009)
Tobacco	Smokeless Tobacco	U.K.	0.15-1.56 mg/kg	McNeill et al. (2006)
	Cigarette Tobacco (^{210}Pb concentrations)	Pakistan	Activity conc.: 7-20 Bq/kg	Tahir and Alaamer (2008)
Toys	Red and yellow painted toy vehicles and tracks	Brazil	500-6,000 mg/kg	Godoi et al. (2009)
	535 PVC and non-PVC toys from day care centers	U.S. (Nevada)	PVC: avg. 325 mg/kg Non-PVC: avg. 89 mg/kg Yellow: 216 mg/kg Non-yellow: 94 mg/kg	Greenway and Gerstenberger (2010)
	Soft plastic toys	India	Average (by city): 21-280 mg/kg	Kumar and Pastore (2007)
	Toy necklace	U.S.	388,000 mg/kg	Meyer et al. (2008)
	Soft plastic toys	Nigeria	2.5-1,445 mg/kg	Omolaoye et al. (2010b)
Vitamins	Vitamins for young children, older children, and pregnant or lactating women	U.S.	Average: Young children: 2.9 µg/day Older children: 1.8 µg/day Pregnant and lactating women: 4.9 µg/day	Mindak et al. (2008)

[a]*Hoodia gordonii*, from Eastern Cape, South Africa *Euterpe oleracea* from Ninole Orchard, Ninole, Hawaii

*Note that the country of origin is not provided because it was not published in the references cited.

4.2 Kinetics

This section summarizes the empirical basis for understanding Pb toxicokinetics in humans. The large amount of empirical information on Pb biokinetics in humans and animal models has been integrated into mechanistic biokinetics models (U.S. EPA, 2006b). These models support predictions about the kinetics of Pb in blood and other selected tissues based on the empirically-based information about Pb biokinetics. In Section 4.3 (and Section 4.2.2.1), Pb biokinetics is described from the context of model predictions.

The discussion of Pb toxicokinetics emphasizes inorganic Pb since this comprises the dominant forms of Pb to which humans in the U.S. are currently exposed as a result of releases of Pb to the atmosphere and historic surface deposition of atmospheric Pb (see Section 3.2.2). The toxicokinetics of organic Pb is only briefly described and a more extensive discussion can be found in the 2006 Pb AQCD. Human exposures to organic

Pb could occur in occupational settings (e.g., during manufacturing of tetraethyl Pb or aviation fuels); however, environmental exposures to organic Pb compounds rarely occur in the U.S. other than in the limited circumstances of those involved in fueling piston-driven aircraft that use leaded aviation gasoline.

4.2.1 Absorption

The major exposure routes of Pb in humans are inhalation and ingestion. Therefore, these exposure routes are important in the discussion of Pb absorption (see Sections 4.2.1.1 and 4.2.1.2). The term "absorption" refers to the fraction of the amount of Pb ingested or inhaled that is absorbed from the respiratory or gastrointestinal tract. The term bioavailability, as it is used in this section, refers to the fraction of the amount of Pb ingested or inhaled that enters the systemic circulation. If properly measured (e.g., time-integrated blood Pb), under most conditions Pb bioavailability is equivalent (or nearly equivalent) to Pb absorption. The time-integrated blood Pb (i.e., the integral of blood Pb over time) provides a useful measure of bioavailability because it reflects both recent Pb absorption as well as contributions from Pb sequestered in soft tissue and bone. Bioaccessibility is a measure of the physiological solubility of Pb in the respiratory or gastrointestinal tract. Pb must become bioaccessible in order for absorption to occur. Processes that contribute to bioaccessibility include physical transformation of Pb particles and dissolution of Pb compounds into forms that can be absorbed (e.g., Pb^{2+}). Bioaccessibility is typically assessed by measuring the fraction of Pb in a sample that can be extracted into a physiological or physiological-like solution (e.g., gastric juice or solution similar to gastric juice).

The 2006 Pb AQCD (U.S. EPA, 2006c) also presented dermal absorption of inorganic and organic Pb compounds, which is generally considered to be much less than by inhalation or ingestion. A study published subsequent to the 2006 Pb AQCD measured rates of absorption of Pb in skin patches harvested from nude mice (Pan et al., 2010). Following application of 12 mg Pb as Pb acetate or Pb nitrate, the absorption rate (measured over a 10-hour observation period) was approximately 0.02 µg Pb/cm^2 per hour. Absorbed Pb was detected in liver and kidney of nude mice following a 120-hr occluded dermal application of approximately 14 mg Pb as either Pb acetate or Pb nitrate. Uptake of Pb into the skin at the site of application was greater when Pb acetate was applied to the skin compared to Pb nitrate; however, liver and kidney Pb concentrations observed at the conclusion of the study (120 hours following the application of Pb) were not different for the two Pb compound. No additional information provides evidence of dermal absorption being a major exposure route of environmental Pb.

4.2.1.1 Inhalation

Systemic absorption of Pb deposited in the respiratory tract is influenced by particle size and solubility, as well as by the pattern of regional deposition within the respiratory tract. Fine particles (<1 µm) deposited in the bronchiolar and alveolar region can be absorbed after extracellular dissolution or can be ingested by phagocytic cells and transported from the respiratory tract (Bailey and Roy, 1994). Larger particles (>2.5 µm) that are primarily deposited in the ciliated airways (nasopharyngeal and tracheobronchial regions) can be transferred by mucociliary transport into the esophagus and swallowed, thus being absorbed via the gut.

Inhaled Pb lodging deep in the respiratory tract seems to be absorbed equally and totally, regardless of chemical form (Morrow et al., 1980; Chamberlain et al., 1978; Rabinowitz et al., 1977). Absorption half-times ($_{t1/2}$) have been estimated for radon decay progeny in adults who inhaled aerosols of Pb and bismuth isotopes generated from decay of ^{220}Rn or ^{222}Rn. The absorption half-time for Pb from the respiratory tract to blood was estimated to be approximately 10 hours in subjects who inhaled aerosols having an activity median particle diameter of approximately 160 nm (range 50-500 nm) (Marsh and Birchall, 1999), and approximately 68 min for aerosols having diameters of approximately 0.3–3 nm (Butterweck et al., 2002). Given the submicron particle size of the exposure, these rates are thought to represent, primarily, absorption from the bronchiolar and alveolar regions of the respiratory tract.

Several studies have quantified the bioaccessibility of Pb in atmospheric PM, based on various in vitro extraction methods. In a study of PM_{10} and $PM_{2.5}$ samples from downtown Vienna, Austria, Falta et al. (2008) used synthetic gastric juice to investigate the bioaccessibility of metals including Pb. The rationale was that inhaled particles in the 2.5-10 µm size range are mostly deposited in the tracheal and bronchial regions of the lung from where they are transported within hours by mucociliary clearance, i.e., they are mainly swallowed. In contrast, the <2.5 µm particles are deposited in the pulmonary alveoli where they can stay for months to years. The study aimed to determine the bioaccessibility of the 2.5-10 µm PM. It is important to note that they do not isolate the 2.5-10 µm size range; instead, they infer the characteristics from the difference between the $PM_{2.5}$ and PM_{10} fractions. The Pb concentrations associated with the two fractions were almost identical, as was the percentage extracted by synthetic gastric juice (86% and 83% Pb for $PM_{2.5}$ and PM_{10} fractions, respectively). The mean daily bioavailable mass was calculated to be 16 ng for the $PM_{2.5-10}$ size range. Since the quantitative clearance of these particles to the stomach was assumed, this value represents an upper estimate for the amount of bioavailable Pb. Niu et al. (2010) determined the bioaccessibility of Pb in fine (100-1,000 nm) and ultrafine-sized (<100 nm) urban airborne PM from two sites

within the city of Ottawa, Canada. For all size fractions, the median Pb concentrations for particles smaller than 10 µm were 8,800 and 7,800 mg/kg for the two different locations. The bioaccessibility was based on ammonium acetate extractability and it was found that, within the fine and ultrafine-size ranges, 13-28% Pb was extracted. The Falta et al. (2008) and Niu et al. (2010) results illustrate that different extraction techniques result in different bioaccessible fractions. The main finding from Niu et al. (2010) was that the highest values (~28% and ~19% for the two different locations) were found for the <57 nm particles, with percent bioaccessibility decreasing with increasing particle size. This result indicated that Pb was potentially most bioaccessible in the ultrafine-size range.

A recent study by Barrett et al. (2010) investigated the solid phase speciation of Pb in urban road dust in Manchester, U.K., and considered the health implications of inhalation and ingestion of such material. Human exposure via inhalation is likely to involve only the finest grained fractions (up to 10 µm) and unfortunately this study characterized only the <38 µm fraction. Pb-goethite and $PbCrO_4$ comprised the largest fractions, 45% and 21% respectively, of Pb in the <38 µm fraction. These forms tend to be less bioaccessible if ingested compared with PbO or Pb acetate because they are less soluble.

The above considerations indicate that the relationship between air Pb exposure and blood Pb will depend on numerous exposure variables (e.g., particle size, solubility, exposure frequency and duration) and physiological variables (age, activity level, transport and absorption in the respiratory tract, blood Pb kinetics). For a detailed discussion of factors affecting particle deposition and retention in the human respiratory tract the reader is referred to Chapter 4 of 2009 PM ISA (U.S. EPA, 2009a). Section 4.2.4 of that document specifically addresses biological factors affecting particle deposition such as activity level and age with an emphasis on children. Mechanistic models provide one means for integrating these variables into predictions of blood Pb – air Pb relationships; although, predictions are subject to simplifications and generalizations made in constructing the models. As an example, the ICRP (Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993) model (see Section 4.3 for a brief description) can be used to predict blood Pb – air Pb slopes for specific direct Pb inhalation exposure scenarios. For a long-term continuous (24 hours/day) exposure of a typical adult male engaged in light exercise (ventilation rate 20-22 m^3/day) to Pb-bearing particles having a 1 µm uniform particle size, the predicted blood Pb – air Pb slopes range from 0.7 µg/dL per µg/m^3 (for low solubility particles; e.g., Pb oxide) to 3 µg/dL per µg/m^3 (for highly soluble Pb; e.g., Pb salts). These slopes were calculated by running ICRP model simulations with varying air concentrations (0.1 - 6 µg/m^3) to achieve a range of blood Pb concentrations up to 10 µg/dL, starting with a baseline of 1.6 µg/dL, and estimating the linear slope of the relationship between blood Pb concentration and air Pb. Empirical estimates of blood

Pb – air Pb slopes for various populations, derived from epidemiological studies, are summarized in Section 4.5.1.

Organic Pb

Alkyl Pb compounds can exist in ambient air as vapors. Inhaled tetraalkyl Pb vapor is nearly completely absorbed following deposition in the respiratory tract. As reported in the 2006 Pb AQCD (U.S. EPA, 2006c), a single exposure to vapors of radioactive (^{203}Pb) tetraethyl Pb resulted in 37% initially deposited in the respiratory tract, of which ~20% was exhaled in the subsequent 48 hours (Heard et al., 1979). In a similar experiment conducted with ^{203}Pb tetramethyl Pb, 51% of the inhaled ^{203}Pb dose was initially deposited in the respiratory tract, of which ~40% was exhaled in 48 hours (Heard et al., 1979).

Estimation of bioavailability of organic Pb is relevant to some aviation fuel exposures (e.g., persons exposed to leaded gasoline used in piston-engine aircraft). Mahaffey (1977) estimated that 40% of inhaled Pb in urban air (largely attributed to combustion of gasoline containing tetraethyllead) is bioavailable to adults. Chamberlain et al. (1975) suggested that 35% of inhaled combustion products of tetraethyl ^{203}Pb fuel [likely to have been a mixture dominated by inorganic Pb halides, but may also have include alkly Pb species (U.S. EPA, 2006b)] are deposited and then retained in adult lungs with a half-life of 6 hours. Fifty percent of that ^{203}Pb was detectable in the blood within 50 hours of inhalation, and the rest was found to deposit in bone or tissue. Chamberlain et al. (1975) estimated that continuous inhalation of Pb in engine exhaust from fuel containing tetraethyllead at a concentration of 0.001 μg/m^3 for a period of months could produce a 1 μg/dL increment in blood Pb.

4.2.1.2 Ingestion

The extent and rate of GI absorption of ingested inorganic Pb are influenced by physiological states of the exposed individual (e.g., age, fasting, nutritional calcium (Ca^{2+}) and iron (Fe) status, pregnancy) and physicochemical characteristics of the Pb-bearing material ingested (e.g., particle size, mineralogy, solubility). Pb absorption in humans may be a capacity-limited process, in which case the percentage of ingested Pb that is absorbed may decrease with increasing rate of Pb intake. Numerous observations of nonlinear relationships between blood Pb concentration and Pb intake in humans provide support for the likely existence of a saturable absorption mechanism or some other capacity-limited process in the distribution of Pb in humans (Sherlock and Quinn, 1986; Sherlock et al., 1984; Pocock et al., 1983; Sherlock et al., 1982). While evidence

for capacity-limited processes at the level of the intestinal epithelium is compelling, the dose at which absorption becomes appreciably limited in humans is not known.

In adults, estimates of absorption of ingested water-soluble Pb compounds (e.g., Pb chloride, Pb nitrate, Pb acetate) range from 3 to 10% in fed subjects (Maddaloni et al., 1998; Watson et al., 1986; James et al., 1985; Heard and Chamberlain, 1982; Rabinowitz et al., 1980). The absence of food in the GI tract increases absorption of water-soluble Pb in adults. Reported estimates of soluble Pb absorption range from 26 to 70% in fasted adults (Maddaloni et al., 1998; James et al., 1985; Blake et al., 1983; Heard and Chamberlain, 1982; Rabinowitz et al., 1980). Reported fed:fasted ratios for soluble Pb absorption in adults range from 0.04 to 0.2 (James et al., 1985; Blake et al., 1983; Heard and Chamberlain, 1982; Rabinowitz et al., 1980).

Limited evidence demonstrates that GI absorption of water-soluble Pb is higher in children than in adults. Estimates derived from dietary balance studies conducted in infants and children (ages 2 weeks to 8 years) indicate that ~40-50% of ingested Pb is absorbed (Ziegler et al., 1978; Alexander et al., 1974). Experimental studies provide further evidence for greater absorption of Pb from the gut in young animals compared to adult animals (Aungst et al., 1981; Kostial et al., 1978; Pounds et al., 1978; Forbes and Reina, 1972). The mechanisms for an apparent age difference in GI absorption of Pb have not been completely elucidated and may include both physiological and dietary factors (Mushak, 1991). To further investigate the effects of the presence of food in the GI tract on Pb absorption, children (3-5 years old) who ate breakfast had lower blood Pb levels compared to children who did not eat breakfast (Liu et al., 2011a). This difference persisted after controlling for nutritional variables (blood iron [Fe], calcium [Ca^{2+}], copper [Cu], magnesium [Mg], zinc [Zn]). This observation may be explained by lower GI absorption of Pb ingested with or in close temporal proximity to meals. Direct evidence for meals lowering GI absorption of Pb has also been reported for adults (Maddaloni et al., 1998; James et al., 1985).

Nutritional interactions of Pb with dietary elements (e.g., Fe, Ca^{2+}, Zn) are complex. Pb competes with other elements for transport and binding sites that can result in adjustments of homeostatic regulators to absorb and retain needed elements. Additionally, low levels of macronutrients may alter Pb bioaccessibility in the GI tract. Genetic variation in absorption and metabolism may modify all of the above.

Children who are iron-deficient have higher blood Pb concentrations than similarly exposed iron-replete children, suggesting that iron deficiency may result in higher Pb absorption or, possibly, other changes in Pb biokinetics that contribute to altered blood Pb concentrations (Schell et al., 2004; Marcus and Schwartz, 1987; Mahaffey and Annest, 1986). Studies conducted in animal models have provided direct evidence for

interactions between iron deficiency and increased Pb absorption, perhaps by enhancing binding of Pb to iron-binding proteins in the intestine (Bannon et al., 2003; Morrison and Quarterman, 1987; Barton et al., 1978b). An analysis of data from a sample 448 woman (age 20-55 years) did not find a significant association between iron body stores (indicated from serum ferritin concentration) and blood Pb concentrations, although depleted irons stores (serum ferritin of <12 µg/L) was associated with higher blood concentrations of Cd, cobalt (Co) and manganese (Mn) higher (Meltzer et al., 2010).The effects of iron nutritional status on blood Pb include changes in blood Pb concentrations in association with genetic variation in genes involved in iron metabolism. For example, genetic variants in the hemochromatosis (HFE) and transferrin genes are associated with higher blood Pb concentrations in children (Hopkins et al., 2008). In contrast, HFE gene variants are associated with lower bone and blood Pb levels in elderly men (Wright et al., 2004).

Several studies have suggested that dietary Ca^{2+} may have a protective role against Pb by decreasing absorption of Pb in the GI tract and by decreasing the mobilization of Pb from bone stores to blood. In experimental studies of adults, absorption of a single dose of Pb (100-300 µg Pb chloride) was lower when the Pb was ingested together with Ca^{2+} carbonate (0.2 g Ca^{2+} carbonate) than when the Pb was ingested without additional Ca^{2+} (Blake and Mann, 1983; Heard and Chamberlain, 1982). A similar effect of Ca^{2+} occurs in rats (Barton et al., 1978a). Similarly, an inverse relationship was observed between dietary Ca^{2+} intake and blood Pb concentration in children, suggesting that children who are Ca^{2+}-deficient may absorb more Pb than Ca^{2+}-replete children (Elias et al., 2007; Schell et al., 2004; Mahaffey et al., 1986; Ziegler et al., 1978). These observations suggest that Ca^{2+} and Pb share and may compete for common binding and transport mechanisms in the small intestine which are regulated in response to dietary Ca^{2+} and Ca^{2+}-body stores (Fullmer and Rosen, 1990; Bronner et al., 1986). However, animal studies have also shown that multiple aspects of Pb toxicokinetics are affected by Ca^{2+} nutritional status. For example, feeding rats a Ca^{2+} deficient diet is associated with increased Pb absorption, decreased whole body Pb clearance, and increased volume of distribution of Pb (Aungst and Fung, 1985). These studies suggest that associations between Ca^{2+} nutrition and blood Pb that have been observed in human populations may not be solely attributable to effects of Ca^{2+} nutrition on Pb absorption. Other potential mechanisms by which Ca^{2+} nutrition may affect blood Pb and Pb biokinetics include effects on bone mineral metabolism and renal function.

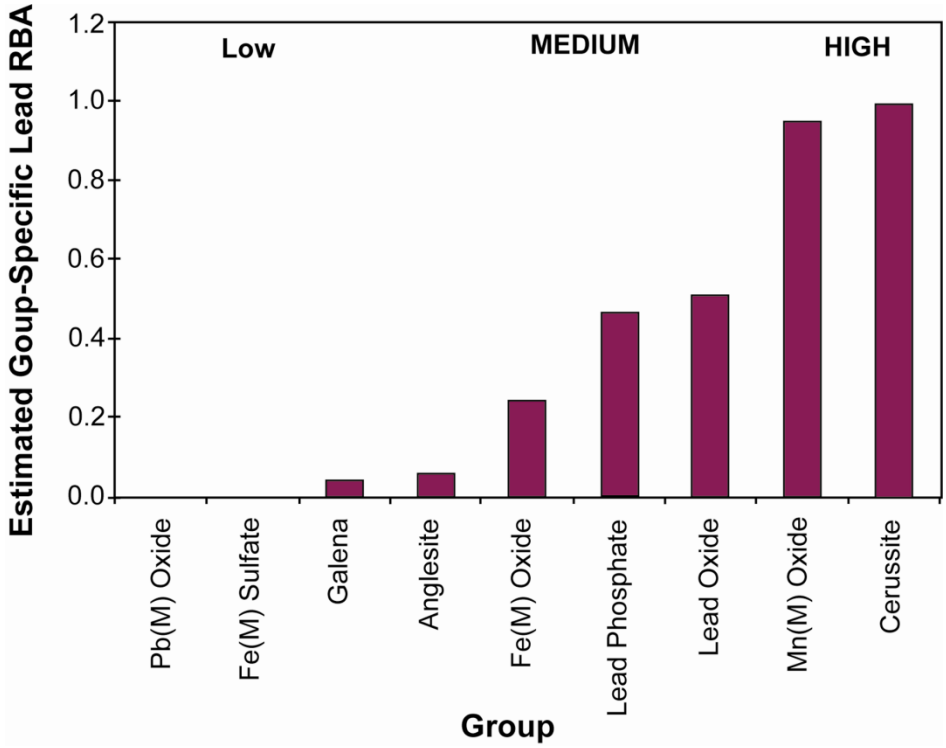
Blood Pb concentrations in young children have also been shown to increase in association with lower dietary Zn levels (Schell et al., 2004). Mechanisms for how Zn affects blood Pb concentration, i.e., whether it involves changes in absorption or changes in distribution and/or elimination of Pb, have not been determined.

Dissolution of Pb from the soil/mineralogical matrix in the stomach appears to be the major process that renders soil Pb bioaccessible for absorption in the GI tract. Absorption of Pb has been shown to vary depending upon the Pb mineralogy and physical characteristics of the Pb in the soil (e.g., encapsulated or exposed) and size of the Pb-bearing grains. GI absorption of larger Pb-containing particles (>100 μm) tends to be lower than smaller particles (Healy et al., 1992; Barltrop and Meek, 1979). Absorption of Pb in soils and dust has been most extensively studied in the in vivo swine model. Gastric function of swine is thought to be sufficiently similar to that of humans to justify use of swine as a model for assessing factors that may affect GI absorption of Pb from soils in humans (Juhasz et al., 2009; U.S. EPA, 2007b; Casteel et al., 2006; Casteel et al., 1997; Weis and Lavelle, 1991). Other practical advantages of the swine model over rodent models have been described, and include: absence of coprophagia; ease with which Pb dosing can be administered and controlled; and higher absorption fraction of soluble Pb (e.g., Pb acetate) in swine, which is more similar to humans than rats (Smith et al., 2009a). The swine studies measure blood and/or tissue Pb (e.g., kidney, liver, bone) concentrations following oral dosing of swine with either soil or with a highly water soluble and fully bioaccessible form of Pb (e.g., Pb acetate). A comparison of the internal concentrations of Pb under these two conditions provides a measure of the bioavailability (i.e., absorption) of Pb in soil relative to that of Pb acetate, which is typically referred to as relative bioavailability (RBA). Relative bioavailability measured in the swine assay is equivalent to the ratio of the absorbed fraction (AF) of ingested dose of soil Pb to that of water-soluble Pb acetate (e.g., RBA = $AF_{Soil\ Pb}/AF_{Pb\ acetate}$).

Collectively, published studies conducted in swine have provided 39 estimates of Pb RBA for 38 different soil or "soil-like" test materials (Bannon et al., 2009; Smith et al., 2009a; Casteel et al., 2006; Marschner et al., 2006). The mean of RBA estimates from 25 soils is 0.49 (± 0.29[SD]), median is 0.51, and 5th to 95th percentile range is 0.12 to -0.89. RBA estimates for soils collected from 8 firing ranges were approximately 1.0 (Bannon et al., 2009). The relatively high RBA for the firing range soils may reflect the high abundance of relatively un-encapsulated Pb carbonate (30-90% abundance) and Pb oxide (1-60%) in these soils. Similarly, a soil sample (low Pb concentration) mixed with a NIST paint standard (55% Pb carbonate, 44% Pb oxide) also had a relatively high bioavailability (0.72) (Casteel et al., 2006). Samples of smelter slag, or soils in which the dominant source of Pb was smelter slag, had relatively low RBA (0.14 – 0.40, n = 3), as did a sample from a mine tailings pile (RBA = 0.06), and a sample of finely ground galena mixed with soil (Casteel et al., 2006).

Based on data for 18 soil materials assayed in swine, RBA of Pb mineral phases were categorized into "low" (<0.25 [25%]), "medium" (0.25-0.75 [25 to 75%]), and "high" (>0.75 [75%]) categories (Casteel et al., 2006). Figure 4-3 shows some of the materials

that fall into these three categories. Mineral phases observed in mineralogical wastes can be expected to change over time (i.e., weathering), which could change the RBA over time. The above observations in swine are supported by various studies conducted in rats that have found RBA of Pb in soils to vary considerably and to be less than 1.0 (Smith et al., 2009a, 2008; Freeman et al., 1996; Freeman et al., 1994; Freeman et al., 1992).



Note: based on results from juvenile swine assays.

Figure 4-3 Estimated relative bioavailability (RBA, compared to Pb acetate) of ingested Pb in mineral groups.

Drexler and Brattin (2007) developed an in vitro bioaccessibility (IVBA) assay for soil Pb that utilizes extraction fluid comprised of glycine, deionized water, and hydrochloric acid at a pH of 1.50 that is combined with sieved test material (<250 μm) for 1 hour. The assay was tested for predicting in vivo RBA of 18 soil-like test materials that were assayed in a juvenile swine assay (Casteel et al., 2006). A regression model relating IVBA and RBA was derived based on these data (Equation 4-1):

$$\mathbf{RBA} = (\mathbf{0.878} \times \mathbf{IVBA}) - \mathbf{0.028}$$

Equation 4-1

where RBA and IVBA are expressed as fractions (i.e., not as percent). The weighted r^2 for the relationship (weighted for error in the IVBA and RBA estimates) was 0.924 ($p < 0.001$). The IVBA assay reported in Drexler and Brattin (2007) has been identified by the U.S. EPA as a validated method for predicting RBA of Pb in soils for use in risk assessment (U.S. EPA, 2007e). A review of soil Pb RBA estimates made using the IVBA assay described above and Equation 4-1 identified 270 estimates of Pb RBA in soils obtained from 11 hazardous waste sites. The mean for the site-wide RBA estimates (n = 11 sites) was 0.57 (SD 0.15), median was 0.63, and 5th to 95th percentile range was 0.34 to 0.71.

Equation 4-1 cannot be reliably extrapolated to other in vitro assays that have been developed for estimating Pb bioaccessibility without validation against in vivo RBA measurements made on the same test materials. Comparisons of outcomes among different in vitro assays applied to the same soil test materials have found considerable variability in IVBA estimates (Juhasz et al., 2011; Smith et al., 2011; Saikat et al., 2007; Van de Wiele et al., 2007). This variability has been attributed to differences in assay conditions, including pH, liquid:soil ratios, inclusion or absence of food material, and differences in methods used to separate dissolved and particle-bound Pb (e.g., centrifugation versus filtration). Smith et al. (2011) found that algorithms for predicting RBA based on two different IVBA assays did not yield similar predictions of RBA when applied to the same material. Given the dependence of IVBA outcomes on assay conditions, in vitro assays used to predict in vivo RBA should be evaluated against in vivo RBA estimates to quantitatively assess uncertainty in RBA predictions (U.S. EPA, 2007e).

Absorption of Pb in house dusts has not been rigorously evaluated quantitatively in humans or in experimental animal models. The RBA for paint Pb mixed with soil was reported to be approximately 0.72 (95% CI: 0.44, 0.98) in juvenile swine, suggesting that paint Pb dust reaching the gastrointestinal tract maybe highly bioavailable (Casteel et al.,

2006). The same material yielded a bioaccessibility value (based on IVBA assay) of 0.75 (Drexler and Brattin, 2007), which corresponds to a predicted RBA of 0.63, based on Equation 4-1. A review of indoor Pb RBA estimates made using the IVBA assay and Equation 4-1 identified 100 estimates of Pb RBA in dusts obtained from two hazardous waste sites. Mean Pb RBAs for the Herculaneum site were 0.47 (SD 0.07, 10 samples) for indoor dust and 0.69 (SD 0.03, 12 samples) for soil. At the Omaha site, mean Pb RBAs were 0.73 (SD 0.10, 90 samples) for indoor dust and 0.70 (SD 0.10, 45 samples) for soil. Yu et al. (2006) applied an IVBA method to estimate bioaccessibility of Pb in house dust samples collected from 15 urban homes. Homes were selected for inclusion in this study based on reporting to the state department of health of at least on child with a blood Pb concentration >15 µg/dL and Pb paint dust may have contributed to indoor dust Pb. The mean IVBA was 0.65 (SD 0.08, age: 52.5 to 77.2 months).

The above results, and the IVBA assays used in studies of interior dust, have not been evaluated against in vivo RBA estimates for dust samples. Although, expectations are that a validated IVBA methodology for soil would perform well for predicting RBA of interior dust, this validation has not actually been experimentally confirmed. Factors that may affect in vivo predictions of RBA of interior dust Pb could include particle size distribution of interior dust Pb and the composition of the dust matrix, which may be quite different from that of soil.

Other estimates of bioaccessibility of Pb in house dusts have been reported, based on results from in vitro extraction assays that have not been validated for predicting in vivo bioavailability. Bioaccessibility assays that sequentially extract soil at gastric pH followed by intestinal pH tend to show higher bioaccessibility of soil and dust Pb when incubated at gastric conditions (Juhasz et al., 2011; Lu et al., 2011; Smith et al., 2011; Roussel et al., 2010; Yu et al., 2006). Yu et al. (2006) dissolved Pb dust, obtained from vacuuming carpet samples into simulated gastric and intestinal acids (also Section 4.1.3.2). The carpet samples were obtained from homes located in northern New Jersey. Pb concentration in carpet ranged from 209 to 1,770 mg/kg dust, with 52-77% of Pb dissolving in simulated gastric acid and 5-32% dissolving in simulated intestinal acids. In a similar test in the U.K., Turner and Simmonds (2006) observed median Pb dust concentrations of 178 mg/kg with approximately 80% bioaccessibility in simulated gastric acid. Jin et al. (2005) observed that bioaccessibility of Pb in soil was proportional to the soil acidity and organic matter content of the soil.

4.2.2 Distribution

A simple conceptual representation of Pb distribution is that it contains a fast turnover pool, comprising mainly soft tissue, and a slow pool, comprising mainly skeletal tissues (Rabinowitz et al., 1976). The highest soft tissue concentrations in adults occur in liver and kidney cortex (Gerhardsson et al., 1995; Oldereid et al., 1993; Gerhardsson et al., 1986; Barry, 1975; Gross et al., 1975). Pb in blood (i.e., plasma) exchanges with both of these compartments.

4.2.2.1 Blood

Blood comprises ~1% of total Pb body burden. Pb in blood is found primarily (>99%) in the RBCs (Smith et al., 2002; Manton et al., 2001; Bergdahl et al., 1999; Bergdahl et al., 1998; Hernandez-Avila et al., 1998; Bergdahl et al., 1997a; Schutz et al., 1996). δ-aminolevulinic acid dehydratase (ALAD) is the primary binding ligand for Pb in erythrocytes (Bergdahl et al., 1998; Xie et al., 1998; Bergdahl et al., 1997a; Sakai et al., 1982). Two other Pb-binding proteins have been identified in the RBC, a 45 kDa protein (K_{max} 700 µg/dL; K_d 5.5 µg/L) and a smaller protein band having a molecular weight of <10 kDa (Bergdahl et al., 1998; Bergdahl et al., 1997a; Bergdahl et al., 1996). Of the three principal Pb-binding proteins identified in RBCs, ALAD has the strongest affinity for Pb (Bergdahl et al., 1998) and appears to dominate the ligand distribution of Pb (35 to 84% of total erythrocyte Pb) at blood Pb levels below 40 µg/dL (Bergdahl et al., 1998; Bergdahl et al., 1996; Sakai et al., 1982). Pb binding to ALAD is saturable; the binding capacity was estimated to be ~850 µg/dL RBCs (or ~40 µg/dL whole blood) and the apparent dissociation constant has been estimated to be ~1.5 µg/L (Bergdahl et al., 1998). Hematocrit is somewhat higher in the neonate at birth (51%) than in later infancy (35% at 6 months), which may lead to a decrease in the total binding capacity of blood over the first 6 months of life that results in a redistribution of Pb among other tissues (Simon et al., 2007).

Saturable binding to RBC proteins contributes to an increase in the plasma/blood Pb ratio with increasing blood Pb concentration and curvature to the blood Pb–plasma Pb relationship (Rentschler et al., 2012; Kang et al., 2009; Jin et al., 2008; Barbosa et al., 2006b; Smith et al., 2002; Manton et al., 2001; Bergdahl et al., 1999; Bergdahl et al., 1998; Bergdahl et al., 1997b; DeSilva, 1981). An example of this is shown in Figure 4-4. Saturable binding of Pb to RBC proteins has several important consequences. As blood Pb increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues. This change in distribution of Pb contributes to a curvature in the

relationship between Pb intake (at constant absorption fraction) and blood Pb concentration. Plasma Pb also exhibits faster kinetics. Following exposures of 5 adults that resulted in relatively high blood Pb concentrations (56-110 µg/dL), the initial (fast-phase) elimination half-time for plasma Pb (38 ± 20 [SD] days) was approximately half that of blood (81 ± 25 days) (Rentschler et al., 2012).

Typically, at blood Pb concentrations <100 µg/dL, only a small fraction (<1%) of blood Pb is found in plasma (Marcus, 1985; Manton and Cook, 1984; DeSilva, 1981). However, as previously noted, plasma Pb may be the more biologically labile and toxicologically effective fraction of the circulating Pb. Approximately 40-75% of Pb in the plasma is bound to proteins, of which albumin appears to be the dominant ligand (Al-Modhefer et al., 1991; Ong and Lee, 1980a). Pb in serum that is not bound to protein exists largely as complexes with low molecular weight sulfhydryl compounds (e.g., cysteine, homocysteine) and other ligands (Al-Modhefer et al., 1991).

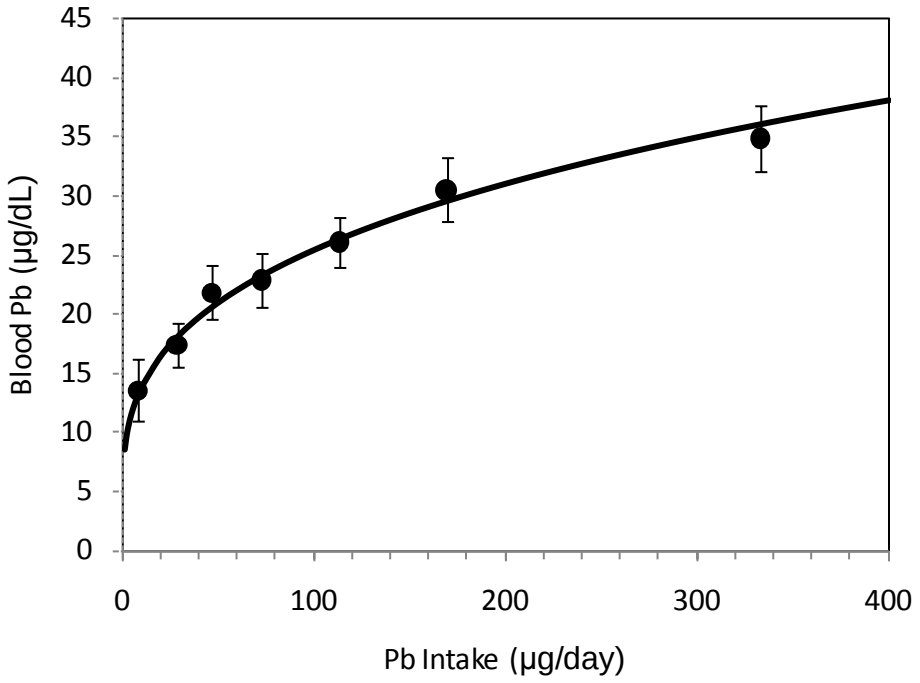
Figure 4-4 Plot of blood and plasma Pb concentrations measured in adults and children.

As shown in Figure 4-4, the limited binding capacity of Pb binding proteins in RBCs produces a curvilinear relationship between blood and plasma Pb concentration. The limited binding capacity of RBC binding proteins also confers, or at least contributes, to a curvilinear relationship between Pb intake and blood Pb concentration. A curvilinear relationship between Pb intake and blood Pb concentration has been observed in children (Sherlock and Quinn, 1986; Lacey et al., 1985; Ryu et al., 1983). As shown in Figure 4-5, the relationship becomes pseudo-linear at relatively low daily Pb intakes (i.e., <10 µg/day/kg) and at blood Pb concentrations <25 µg/dL.



Data represent mean and standard errors for intake; the line is the regression model (blood Pb = 3.9 + 2.43 (Pb intake [µg/week]$^{1/3}$).

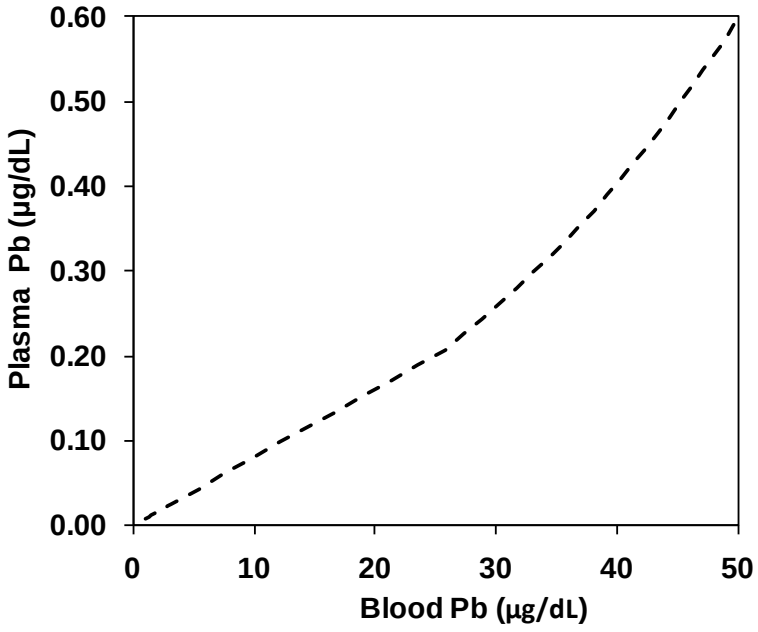
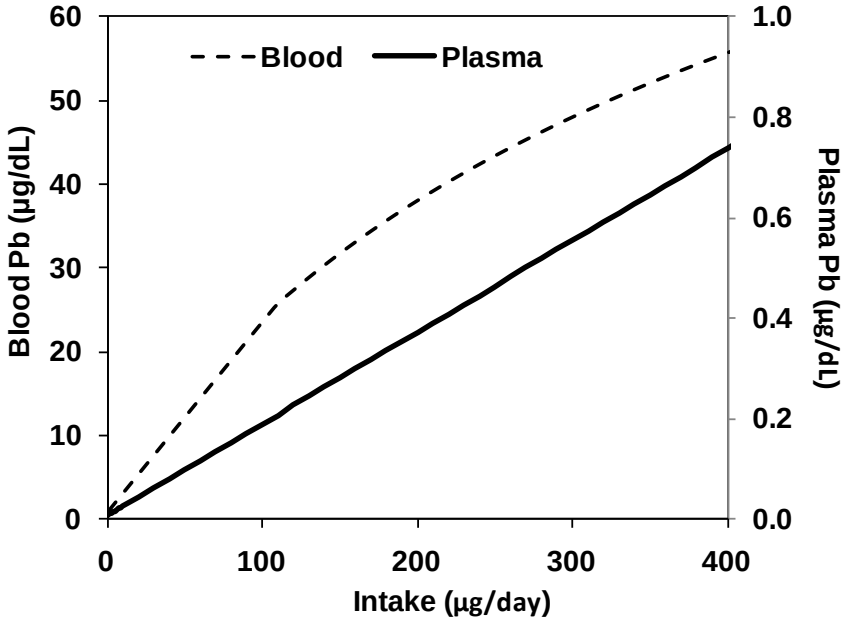
Figure 4-5 Relationship between Pb intake and blood Pb concentration in infants (n = 105, age 13 weeks, formula-fed).

Figure 4-6 shows the predicted relationship between quasi-steady state blood and plasma Pb concentrations in a 4-year old child using the ICRP model [(Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993), see Section 4.3 for a brief description of the ICRP model]. The abrupt inflection point that occurs at approximately 25 µg/dL blood Pb is an artifact of the numerical approach to simulate the saturation of binding using discontinuous first-order rate constants for uptake and exit of Pb from the RBC. A continuous function of binding sites and affinity, using empirical estimates of both parameters, yield a similar but continuous curvature in the relationship (Bergdahl et al., 1998; O'Flaherty, 1995). Nevertheless, either approach predicts a pseudo-linear relationship at blood Pb concentrations below approximately 25 µg/dL which, in this model, corresponds to an intake of approximately 100 µg/day (absorption rate ≈ 30 µg/day) (upper panel). An important consequence of the limited Pb-binding capacity of RBC proteins is that the plasma Pb concentration will continue to grow at a linear rate above the saturation point for RBC protein binding. One implication of this is that a larger fraction of the Pb in blood will become available to distribute to brain and other Pb-responsive tissues as blood Pb increases. This could potentially contribute to non-linearity in dose-response relationships in studies in which blood Pb is the used as the internal dose metric.





Note: Model simulations are for a 4-year old having from birth a constant Pb intake of between 1 and 400 µg/day. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-6 Simulation of quasi-steady state blood and plasma Pb concentrations in a child (age 4 years) associated with varying Pb ingestion rates.

Studies conducted in swine provide additional evidence in support of RBC binding kinetics influencing distribution of Pb to tissues. In these studies, the relationship between the ingested dose of Pb and tissue Pb concentrations (e.g., liver, kidney, bone) was linear, whereas, the relationship between dose and blood Pb was curvilinear with the slope decreasing as the dose increased (Casteel et al., 2006). Saturable binding of Pb to RBC proteins also contributes to a curvilinear relationship between urinary Pb excretion and plasma Pb concentration (Section 4.2.3) (Besser et al., 2008; Bergdahl et al., 1997b).

4.2.2.2 Bone

The dominant compartment for Pb in the body is in bone. In human adults, more than 90% of the total body burden of Pb is found in the bones, whereas bone Pb accounts for just under 60% of the body burden in infants less than a year old and just over 70% of the body burden in older children (Barry, 1975). Bone is comprised of two main types, cortical (or compact) and trabecular (or spongy or cancellous). The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80 to 20 percent (O'Flaherty, 1998; Leggett, 1993; ICRP, 1973).

The exchange of Pb from plasma to the bone surface is a rapid process (i.e., adult $t_{1/2}$ =0.19 and 0.23 hours for trabecular and cortical bone, respectively) (Leggett, 1993). Some Pb diffuses from the bone surface to deeper bone regions (adult $t_{1/2}$=150 days) where it is relatively inert (in adults) and part of a “nonexchangeable” (removed only through bone resorption/remodeling) pool of Pb in bone (Leggett, 1993).

Pb distribution in bone includes uptake into cells that populate bone (e.g., osteoblasts, osteoclasts, osteocytes) and exchanges with proteins and minerals in the extracellular matrix (Pounds et al., 1991). Pb forms highly stable complexes with phosphate and can replace calcium in the calcium-phosphate salt, hydroxyapatite, which comprises the primary crystalline matrix of bone (Meirer et al., 2011; Brès et al., 1986; Miyake, 1986; Verbeeck et al., 1981). Several intracellular kinetic pools of Pb have been described in isolated cultures of osteoblasts and osteoclasts which appear to reflect physiological compartmentalization within the cell, including membranes, mitochondria, soluble intracellular binding proteins, mineralized Pb (i.e., hydroxyapatite) and inclusion bodies (Long et al., 1990; Pounds and Rosen, 1986; Rosen, 1983). Approximately 70-80% of Pb taken up into isolated primary cultures of osteoblasts or osteocytes is associated with mitochondria and mineralized Pb (Pounds et al., 1991).

Pb accumulates in bone regions having the most active calcification at the time of exposure. Pb accumulation is thought to occur predominantly in trabecular bone during childhood and in both cortical and trabecular bone in adulthood (Aufderheide and

Wittmers, 1992). Early Pb uptake in children is greater in trabecular bone due to its larger surface area and higher metabolic rate. With continued exposure, Pb concentrations in bone may increase with age throughout the lifetime beginning in childhood, indicative of a relatively slow turnover of Pb in adult bone (Park et al., 2009c; Barry and Connolly, 1981; Barry, 1975; Gross et al., 1975; Schroeder and Tipton, 1968). The cortical and trabecular bones have distinct rates of turnover and Pb release. For example, tibia has a turnover rate of about 2% per year whereas trabecular bone has a turnover rate of more than 8% per year in adults (Rabinowitz, 1991).

A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, most of the Pb acquired early in life is not permanently fixed in the bone (60-65%) (O'Flaherty, 1995; Leggett, 1993; ICRP, 1973). However, some Pb accumulated in bone does persist into later life. McNeill et al. (2000) compared tibia Pb levels and cumulative blood Pb indices in a population of 19- to 29-year-olds who had been highly exposed to Pb in childhood from the Bunker Hill, Idaho smelter; they concluded that Pb from exposure in early childhood had persisted in the bone matrix until adulthood.

Additional discussion of the Pb in bone and its mobilization are provided in other sections of this chapter. Maternal mobilization of Pb from the bone to the fetus is discussed in Section 4.2.2.4. The relationship between Pb in blood and bone is discussed in Section 4.3.5.

4.2.2.3 Soft Tissues

Most of the Pb in soft tissue is in liver and kidney (Gerhardsson et al., 1995; Oldereid et al., 1993; Gerhardsson et al., 1986; Barry, 1981, 1975; Gross et al., 1975). Presumably, the Pb in these soft tissues (i.e., kidney, liver, and brain) exists predominantly bound to protein. High affinity cytosolic Pb-binding proteins have been identified in rat kidney and brain (DuVal and Fowler, 1989; Fowler, 1989). The Pb-binding proteins in rat are cleavage products of α2μ globulin, a member of the protein superfamily known as retinol-binding proteins that are generally observed only in male rats (Fowler and DuVal, 1991). Other high-affinity Pb-binding proteins (K_d ~14 nM) have been isolated in human kidney, two of which have been identified as a 5 kDa peptide, thymosin 4 and a 9 kDa peptide, acyl-CoA binding protein (Smith et al., 1998). Pb also binds to metallothionein, but does not appear to be a significant inducer of the protein in comparison with the inducers Cd and Zn (Waalkes and Klaassen, 1985; Eaton et al., 1980).

The liver and kidneys rapidly accumulate systemic Pb ($t_{1/2}$=0.21 and 0.41 hours, respectively), which amounts to 10-15% and 15-20% of intravenously injected Pb, respectively (Leggett, 1993). A linear relationship in dose-tissue Pb concentrations for kidney and liver has been demonstrated in swine, dogs, and rats (Smith et al., 2008; Casteel et al., 2006; Casteel et al., 1997; Azar et al., 1973). In contrast to Pb in bone, which accumulates Pb with continued exposure in adulthood, concentrations in soft tissues (e.g., liver and kidney) are relatively constant in adults (Treble and Thompson, 1997; Barry, 1975), reflecting a faster turnover of Pb in soft tissue relative to bone.

4.2.2.4 Fetus

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood Pb to maternal blood Pb ratios (i.e., cord blood Pb concentration divided by mother's blood Pb concentration). Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL (Amaral et al., 2010; Kordas et al., 2009; Patel and Prabhu, 2009; Carbone et al., 1998; Goyer, 1990; Graziano et al., 1990). In a study of 159 mothers having blood Pb levels of less than 14 µg/dL, based on a linear regression of maternal blood Pb and cord blood Pb, the ratio of cord blood Pb to maternal blood Pb appeared to decrease with decreasing maternal blood Pb from 1.0 at 10 µg/dL to 0.34 at 3 µg/dL (Carbone et al., 1998). A ratio of 0.34 is lower than reported based on mean data in other studies. However, consistent with other studies, the ratio of mean cord blood Pb (4.87 µg/dL) to mean maternal blood Pb (5.81 µg/dL) was 0.84. In addition, the similarity of isotopic ratios in maternal blood and in blood and urine of newly-born infants provide further evidence for placental transfer of Pb to the fetus (Gulson et al., 1999).

Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy (Montenegro et al., 2008; Lamadrid-Figueroa et al., 2006). Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton. Evidence for transfer of maternal bone Pb to the fetus has been provided by stable Pb isotope studies in cynomolgus monkeys exposed during pregnancy. Approximately 7-39% of the maternal Pb burden transferred to the fetus was derived from the maternal skeleton, with the remainder derived from contemporaneous exposure (O'Flaherty, 1998; Franklin et al., 1997). The upper value in the range (39%) represented the one monkey with historical Pb exposure, but received only small amounts of environmental Pb exposure during pregnancy; for the monkeys that received high doses of Pb during pregnancy, the range was lower (7-25%) (O'Flaherty, 1998; Franklin et al., 1997).

4.2.2.5 Organic Pb

Information on the distribution of Pb in humans following exposures to organic Pb is extremely limited. However, as reported in the 2006 Pb AQCD (U.S. EPA, 2006c), the available evidence demonstrates near complete absorption following inhalation of tetraalkyl Pb vapor and subsequent transformation to trialkyl Pb metabolites. One hour following brief inhalation exposures to ^{203}Pb tetraethyl or tetramethyl Pb (1 mg/m^3), ~50% of the ^{203}Pb body burden was associated with liver and 5% with kidney; the remaining ^{203}Pb was widely distributed throughout the body (Heard et al., 1979). The kinetics of ^{203}Pb in blood showed an initial declining phase during the first 4 hours (tetramethyl Pb) or 10 hours (tetraethyl Pb) after the exposure, followed by a reappearance of radioactivity back into the blood after ~20 hours. The high level of radioactivity initially in the plasma indicates the presence of tetraalkyl/trialkyl Pb. The subsequent rise in blood radioactivity, however, probably represents water-soluble inorganic Pb and trialkyl and dialkyl Pb compounds that were formed from the metabolic conversion of the volatile parent compounds (Heard et al., 1979).

Alkyl Pb compounds undergo oxidative dealkylation catalyzed by cytochrome P450 in liver and, possibly, in other tissues. Trialkyl Pb metabolites have been found in the liver, kidney, and brain following exposure to the tetraalkyl compounds in workers (Bolanowska et al., 1967); these metabolites have also been detected in brain tissue of nonoccupational subjects (Nielsen et al., 1978).

4.2.3 Elimination

The rapid-phase (30-40 days) of Pb excretion amounts to 50-60% of the absorbed fraction (Chamberlain et al., 1978; Rabinowitz et al., 1976; Kehoe, 1961a, b, c). Absorbed Pb is excreted primarily in urine and feces, with sweat, saliva, hair, nails, and breast milk being minor routes of excretion (Kehoe, 1987; Chamberlain et al., 1978; Rabinowitz et al., 1976; Griffin et al., 1975; Hursh et al., 1969; Hursh and Suomela, 1968).

Approximately 30% of intravenously injected Pb in humans (40-50% in beagles and baboons) is excreted via urine and feces during the first 20 days following administration (Leggett, 1993). The kinetics of urinary excretion following a single dose of Pb is similar to that of blood (Chamberlain et al., 1978), likely due to the fact that Pb in urine derives largely from Pb in plasma. Evidence for this is the observation that urinary Pb excretion is strongly correlated with the rate of glomerular filtration of Pb (Araki et al., 1986) and plasma Pb concentration (Rentschler et al., 2012; Bergdahl et al., 1997b) (i.e., glomerular

filtration rate × plasma Pb concentration), and both relationships are linear. While the relationship between urinary Pb excretion and plasma Pb concentration is linear, the plasma Pb relationship to blood Pb concentration is curvilinear (as described in Section 4.2.2.1 and demonstrated in Figure 4-6). This relationship contributes to an increase in the renal clearance of Pb from blood with increasing blood Pb concentrations (Chamberlain, 1983). Similarly, a linear relationship between plasma Pb concentration and urinary excretion rate predicts a linear relationship between Pb intake (at constant absorption fraction) and urinary Pb excretion rate, whereas the relationship with blood Pb concentration would be expected to be curvilinear (Section 4.3.6).

Estimates of urinary filtration of Pb from plasma range from 13-22 L/day, with a mean of 18 L/day (Araki et al., 1986; Manton and Cook, 1984; Manton and Malloy, 1983; Chamberlain et al., 1978), which corresponds to half-time for transfer of Pb from plasma to urine of 0.1-0.16 days for a 70-kg adult who has a plasma volume of ~3 L. The rate of urinary excretion of Pb was less than the rate of glomerular filtration of ultrafilterable Pb, suggesting that urinary Pb is the result of incomplete renal tubular re-absorption of Pb in the glomerular filtrate (Araki et al., 1986); although, net tubular secretion of Pb has been demonstrated in animals (Victery et al., 1979; Vander et al., 1977). On the other hand, estimates of blood-to-urine clearance range from 0.03-0.3 L/day with a mean of 0.18 L/day (Diamond, 1992; Araki et al., 1990; Berger et al., 1990; Koster et al., 1989; Manton and Malloy, 1983; Ryu et al., 1983; Chamberlain et al., 1978; Rabinowitz et al., 1973), consistent with a plasma Pb to blood Pb concentration ratio of ~0.005–0.01 L/day (Klotzback et al., 2003). Based on the above differences, urinary excretion of Pb can be expected to reflect the concentration of Pb in plasma and variables that affect delivery of Pb from plasma to urine (e.g., glomerular filtration and other transfer processes in the kidney).

The value for fecal:urinary excretion ratio (~0.5) was observed during days 2-14 following intravenous injection of Pb in humans (Chamberlain et al., 1978; Booker et al., 1969; Hursh et al., 1969). This ratio is slightly higher (0.7-0.8) with inhalation of submicron Pb-bearing PM due to ciliary clearance and subsequent ingestion. The transfer of Pb from blood plasma to the small intestine by biliary secretion in the liver is rapid (adult $t_{1/2}$ = 10 days), and accounts for 70% of the total plasma clearance (O'Flaherty, 1995).

Organic Pb

Pb absorbed after inhalation of tetraethyl and tetramethyl Pb is excreted in exhaled air, urine, and feces (Heard et al., 1979). Fecal:urinary excretion ratios were 1.8 following exposure to tetraethyl Pb and 1.0 following exposure to tetramethyl Pb (Heard et al., 1979). Occupational monitoring studies of workers exposed to tetraethyl Pb showed that tetraethyl Pb is excreted in the urine as diethyl Pb, ethyl Pb, and inorganic Pb (Vural and Duydu, 1995; Zhang et al., 1994; Turlakiewicz and Chmielnicka, 1985).

4.3 Pb Biomarkers

This section describes the biological measurements of Pb and their interpretation as indicators of exposure or body burden.

For any health endpoint of interest, the most useful biomarker of exposure is one that provides information about the Pb dose at the critical target organ and, moreover, reflects the exposure averaging time that is appropriate to the underlying pathogenetic processes (e.g., instantaneous, cumulative over lifetime, or cumulative over a circumscribed age range). In recent studies of Pb and health, the exposure biomarkers most frequently used are Pb in blood and bone. For outcomes other than those relating to hematopoiesis and bone health, these biomarkers provide information about Pb dose that is some distance from the target organ. For example, given that the central nervous system is considered the critical target organ for childhood Pb toxicity, it would be most helpful to be able to measure, in vivo, the Pb concentrations at the cellular site(s) of action in the brain. However, because such measurements are not currently feasible, investigators must rely on measurements of Pb in the more readily accessible but peripheral tissues. The relationship between brain Pb and Pb in each of these surrogate tissues is still poorly understood, although the pharmacokinetics clearly differs among these compartments.

As an exposure biomarker, blood Pb concentration has other limitations. Only about 1% of an individual's total body Pb burden resides in blood. Furthermore, blood consists of several subcompartments. More than 90% of Pb in whole blood is bound to red cell proteins such as ALAD, with the balance in plasma. From a toxicological perspective, the unbound fraction is likely to be the most important subcompartment of blood Pb because it distributes into soft tissues. The concentration of Pb in plasma is much lower than in whole blood (<1%). The greater relative abundance of Pb in whole blood makes its measurement much easier (and more affordable) than measurement of Pb in plasma. The use of whole blood Pb as a surrogate for plasma Pb could be justified if the ratio of whole blood Pb to plasma Pb were well characterized, but this is not so. At least some studies suggest that it varies several-fold among individuals with the same blood Pb level.

Moreover, binding Pb in red blood cells is limited, so the ratio of blood Pb to plasma Pb would be expected to be nonlinear. Thus, interpreting whole blood Pb level as a proxy for plasma Pb level, which, itself, is a proxy for brain Pb level, will result in some exposure misclassification.

Another limitation of blood Pb as an exposure biomarker is that the kinetics of Pb in blood is relatively fast compared to the kinetics of Pb in bone, and therefore, of the whole body burden. Thus, a high blood Pb concentration measured at any given time does not necessarily indicate a high body Pb burden. Similarly, individuals who have the same blood Pb level will not necessarily have similar body burdens or exposure histories. The rate at which blood Pb changes with time/age depends on exposure history due to re-equilibration of Pb stored in the various body pools.

The development of X-ray-fluorescence (XRF) methods for measuring Pb in mineralized tissues offers another approach for characterization and reconstruction of exposure history. Such tissues are long-term Pb storage sites, with a half-life measured in decades and contain ~90% of the total body Pb burden in adults and 70% in children. Thus, bone Pb reflects a long exposure averaging time.

Mechanistic models are used throughout the section as a means to describe basic concepts that derive from the wealth of information on Pb toxicokinetics. Although predictions from models are inherently uncertain, models can serve to illustrate expected interrelationships between Pb intake and tissue distribution that are important in interpreting human clinical and epidemiologic studies. Thus, models serve as the only means available for synthesizing the extensive, but incomplete, knowledge of Pb biokinetics into a holistic representation of Pb biokinetics. Furthermore, models can also be used to make predictions about biokinetics relationships that have not been thoroughly evaluated in experiments or epidemiologic studies. In this way, models can serve as heuristic tools for shaping data collection to improve understanding of Pb biokinetics.

Mechanistic toxicokinetics models can make predictions about hypothetical populations and exposure scenarios. When a model is run as a single simulation, the output represents average outcomes from what is in reality a distribution of possible outcomes that would be expected in the population (or in any single individual) where intra-individual and inter-individual variability in exposure and toxicokinetics exist. More realistic predictions for the population can be developed by running a series of model simulations in which ranges (i.e., distributions) of parameter values are considered that may better represent the population of interest. In this section, only single simulations are used to demonstrate relationships between various biomarkers (e.g., blood Pb and bone Pb) that would apply to a population having “typical” or “average” exposure and toxicokinetics. These single

simulations are used for illustrative purposes to describe general concepts and patterns. Variability would be expected in real populations.

Numerous mechanistic models of Pb biokinetics in humans have been proposed, and these are described in the 2006 Pb AQCD (U.S. EPA, 2006b) and in the supporting literature cited in that report. In this section, for simplicity and for internal consistency, discussion is limited to predictions from a single model, the ICRP Pb biokinetics model (Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993). The ICRP model consists of a systemic biokinetics model (Leggett, 1993) and a human respiratory tract model (ICRP, 1994). The Leggett model simulates age-dependent kinetics of tissue distribution and excretion of Pb ingestion and inhalation intakes. This model was originally developed for the purpose of supporting radiation dosimetry predictions and it has been used to develop cancer risk coefficients for internal radiation exposures to Pb and other alkaline earth elements that have biokinetics similar to those of calcium (ICRP, 1993). Although the ICRP model has not been validated by U.S. EPA as a regulatory model for Pb risk assessment, it has been applied in Pb risk assessment (Abrahams et al., 2006; Lorenzana et al., 2005; Khoury and Diamond, 2003). Portions of the model have been incorporated into an AALM that is being developed by EPA (2005a). In addition to the above considerations regarding previous applications of the ICRP model, the model was selected for use in the ISA because it has several useful features for predicting exposure-body burden relationships. The model simulates blood Pb and tissue Pb concentration dynamics associated with the uptake and elimination phases of exposures of $\geq$ 1 day in duration; and it simulates age-dependent and particle size-dependent deposition and clearance of inhaled Pb in the respiratory tract. These types of simulations can only be approximated with the U.S. EPA IEUBK Model for Pb in children because it simulates exposures in time steps of 1 year (i.e., age-year average exposures); lumps the simulation of deposition, mechanical clearance, and absorption of inhaled Pb into a single absorption term representing the combined processes of gastrointestinal and respiratory tract absorption of inhaled Pb; simulates steady state blood Pb concentrations and was does not allow access to the underlying simulations of tissue Pb concentrations which serve as intermediate variables in the model for predicting steady state blood Pb concentrations. Other models have been developed that allow simulations of tissue Pb concentrations (e.g., O'Flaherty, 1995; Leggett, 1993) and comparisons of these models have been previously described (Maddaloni et al., 2005).

Pb biokinetics in adolescents is poorly characterized by all existing Pb biokinetics models. Individuals undergo rapid changes in sexual development, growth, food and water intake, bone growth and turnover, behavior, etc. during adolescence. There is a paucity of experimental measurements of Pb biomarkers during this time developmental window. The individual biological and kinetic parameters for adolescents are largely interpolated rather than based on solid experimental and toxicological measurements. These deficiencies limit the validity of model predictions in this age group.

4.3.1 Bone-Pb Measurements

For Pb measurements in bone, the most commonly examined bones are the tibia, calcaneus, patella, and finger bone. For cortical bone, the midpoint of the tibia is measured. For trabecular bone, both the patella and calcaneus are measured. The tibia consists of more than 95% cortical bone, the calcaneus and patella comprise more than 95% trabecular bone, and finger bone is a mixed cortical and trabecular bone although the second phalanx is dominantly cortical. Recent studies favor measurement of the patella for estimating trabecular bone Pb, because it has more bone mass and may afford better measurement precision than the calcaneus.

Bone Pb measurements are typically expressed in units of μg Pb per g bone mineral. This convention may potentially introduce variability into the bone Pb measurements related to variation in bone density. Typically, potential associations between bone density and bone Pb concentration are not evaluated in epidemiologic studies (Theppeang et al., 2008a; Hu et al., 2007a). An important consequence of expressing bone Pb measures relative to bone mineral content is that lower bone mineral density is associated with greater measurement uncertainty in bone Pb. This can have important implications for studies in older women for whom low bone mineral density is more common than in other populations including men and younger adults.

Methods of direct analysis of bone tissue samples include flame atomic absorption spectrometry (AAS), anode stripping voltammetry (ASV), inductively coupled plasma atomic emission spectroscopy (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), thermal ionization mass spectrometry (TIMS), synchrotron radiation induced X-ray emission (SRIXE), particle induced X-ray emission (PIXE), and X-ray fluorescence (XRF). Non-invasive, in vivo measurements of bone Pb is achieved with XRF. The upsurge in popularity of the XRF method has paralleled a decline in the use of the other methods. More information on the precision, accuracy, and variability in bone Pb measurements can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

Two main approaches for XRF measurements have been used to measure Pb concentrations in bone, the K-shell and L-shell methods. The K-shell method is the most widely used, as there have been relatively few developments in L-shell devices since the early 1990s. However, Nie et al. (2011a) recently reported on the use of a new portable L-shell device for human in vivo Pb measurements. Advances in L-shell device technology resulted in much higher sensitivity than previous L-shell devices. The new L-shell device showed sensitivity similar to that of K-shell methods (detection limit was approximately 8 µg/g bone mineral with 2 mm of soft tissue overlay targeted bone) and a high correlation with results obtained from K-shell methods (intraclass correlation = 0.65). Behinaen et al. (2011) described application of a 4-detector system ("*clover leaf array*") for the K-shell method that provided higher precision and lower minimum detection limits (MDL) for tibia and calcaneus Pb measurements (3.25 and 4.78 µg/g bone mineral, respectively) compared to measurements made with single detectors (8-12 µg/g and 14-15 µg/g, respectively).

Since 1986, several investigators have reported refinements to hardware and software to improve the precision and accuracy of XRF measurements and there have been a number of investigations into the precision, accuracy and variability in XRF measurements [e.g., (Todd et al., 2002; Todd et al., 2001; Aro et al., 2000; Todd et al., 2000)]. Todd et al. (2000) provided a detailed discussion of factors that influence the variability and measurement uncertainty, including repositioning, sample measurement duration, overlying tissue, operator expertise, detector resolution, and changes to measurement process over time. Some of these aspects were also discussed by Hu et al. (1995). From their cadaver and in vivo measurements, Todd et al. (2000) concluded that the uncertainty in an individual measurement was an underestimate of the standard deviation of replicate measurements, suggesting a methodological deficiency probably shared by most current ^{109}Cd-based K-shell XRF Pb measurement systems. In examining the reproducibility of the bone Pb measurements over a 4½ month period, Todd et al. (2000) also found the average difference between the XRF results from short term and longer term measurements was 1.2 µg/g, indicating only a small amount of variability in the XRF results over a sustained period of time.

In the epidemiologic literature, XRF bone Pb data have typically been reported in two ways: one that involves a methodological approach to assessing the minimum detection limit and the other termed an epidemiologic approach by Rosen and Pounds (1998). In the former approach, a minimum detection limit is defined using various methods, including two or three times the square root of the background counts; one, two, or three times the standard deviation (SD) of the background; or two times the observed median error. This approach relies upon the minimum detection limit to define a quantitative estimate that is of sufficient precision to be included in the statistical analysis, as

demonstrated by Bellinger et al. (1994a), Gerhardsson et al. (1993), and Christoffersson et al. (1986).

With the epidemiologic approach, all values are used (including negative values) to determine the minimum detection limit of an instrument that results in extremely low detection limits. Rosen and Pounds (1998) noted that this approach yields population bone Pb averages that were artificially low. However, not including values that are negative or below the detection limit, or assigning these values a fixed number is also of concern. Using the epidemiologic approach of retaining all point estimates of measured bone Pb concentrations provided the least amount of bias and the greatest efficiency in comparing the mean or median levels of bone Pb of different populations (Kim et al., 1995).

4.3.2 Blood-Pb Measurements

Analytical methods for measuring Pb in blood include AAS, graphite furnace atomic absorption spectrometry (GFAAS), ASV, ICP-AES, and ICP-MS. GFAAS and ASV are generally considered to be the methods of choice (Flegal and Smith, 1995). Limits of detection for Pb using AAS are on the order of 5-10 µg/dL for flame AAS measurements and approximately 0.1 µg/dL for flameless AAS measurements (Flegal and Smith, 1995; NIOSH, 1994). A detection limit of 0.005 µg/dL has been achieved for Pb in blood samples analyzed by GFAAS.

For measurement of Pb in plasma, ICP-MS provides sufficient sensitivity (Schutz et al., 1996). While the technique has been applied to assessing Pb exposures in adults, ICP-MS has not received widespread use in epidemiologic studies.

The primary binding ligand for Pb in RBC, ALAD, is encoded by a single gene in humans that is polymorphic in two alleles (ALAD1 and ALAD2) (Scinicariello et al., 2007). Since the ALAD1 and ALAD 2 alleles can be co-dominantly expressed, 3 different genotypes (ALAD 1-1, ALAD 1-2, and ALAD 2-2) are possible. The ALAD 1-1 genotype is the most common. Scinicariello et al. (2010) tested genotypes in civilian, non-institutionalized U.S. individuals that participated as part of NHANES III from 1988–1994 and found that 15.6% of non-Hispanic whites, 2.6% non-Hispanic blacks, and 8.8% Mexican Americans carried the ALAD2 allele.

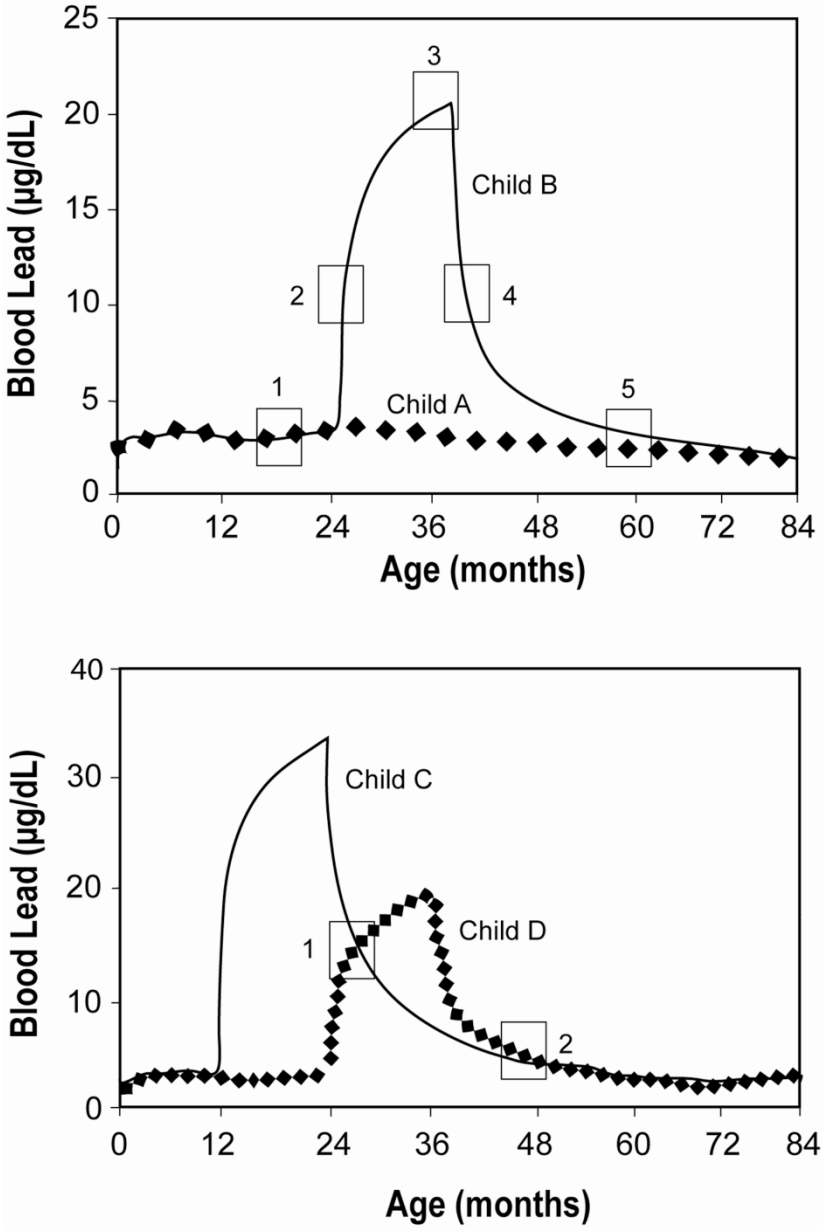
The 2006 Pb AQCD (U.S. EPA, 2006c) reported that many studies have shown that, with similar exposures to Pb, individuals with the ALAD-2 allele have higher blood Pb levels than those without (Kim et al., 2004; Pérez-Bravo et al., 2004; Bergdahl et al., 1997b; Smith et al., 1995a; Wetmur, 1994; Wetmur et al., 1991b; Astrin et al., 1987). More

recent meta analyses provide further support for ALAD2 carriers having higher blood Pb levels than ALAD1-1 homozygotes (Scinicariello et al., 2007; Zhao et al., 2007). The mechanism for this association may be higher Pb binding affinity of ALAD2. Although, this interpretation would be consistent with the structural differences that result in greater electronegativity of ALAD1 compared to ALAD2 (Wetmur, 1994; Wetmur et al., 1991a), measurements of Pb binding affinity to ALAD1 and ALAD2 (i.e., Pb^{2+} displacement of Zn^{2+} binding to recombinant ALAD1 and ALAD2) have not revealed differences in Pb binding affinity (Jaffe et al., 2000). In a meta-analysis of 24 studies, Scinicariello et al. (2007), observed the greatest differences for ALAD2 compared to ALAD1 in highly exposed adults with little difference among environmentally-exposed adults; large differences were also observed for children at low exposures. However, there are few studies that evaluated children and the largest study contributing to the meta analysis may have been influenced by selection bias (Scinicariello et al., 2007). Individual studies find similar results in occupationally-exposed adults, with blood Pb levels being higher in individuals with ALAD2 alleles (Miyaki et al., 2009; Shaik and Jamil, 2009). A subsequent meta analysis of adult data from NHANES III did not find any differences in blood Pb level between all carriers of either the ALAD 1-1 or ALAD 1-2/2-2 allele (Scinicariello et al., 2010). Other studies provide further support for no blood Pb differences among ALAD1 and ALAD2 carriers (Sobin et al., 2009; Rabstein et al., 2008; Montenegro et al., 2006; Wananukul et al., 2006) or lower blood Pb levels for individuals with ALAD 1-2/2-2 (Krieg et al., 2009; Chia et al., 2006).

Genetic polymorphism in the gene that encodes for peptide transporter 2 (PEPT2) has been associated with variability in blood Pb concentrations in children (Sobin et al., 2009). PEPT2 expression in the brain and renal proximal tubule has been associated with transport of di- and tri-peptides and may function in the transport of δ-ALA into brain and renal tubular re-absorption of peptides. The PRPT2*2 polymorphism was associated with increased blood Pb concentrations in a sample of 116 children of Mexican-American/Hispanic heritage (age 4-12 years, mean blood Pb concentration 3-6 µg/dL).

Analyses of serial blood Pb concentrations measured in longitudinal epidemiologic studies found relatively strong correlations (e.g., r = 0.5-0.8) among each child's individual blood Pb concentrations measured after 6-12 months of age (Schnaas et al., 2000; Dietrich et al., 1993a; McMichael et al., 1988; Otto et al., 1985; Rabinowitz et al., 1984). These observations suggest that, in general, exposure characteristics of an individual child (e.g., exposure levels and/or exposure behaviors) tend to be relatively constant across age. However, a single blood Pb measurement may not distinguish between a history of long-term lower-level Pb exposure from a history that includes higher acute exposures (Mushak, 1998). This concept is illustrated in Figure 4-7. Two hypothetical children are simulated. Child A has a relatively constant Pb intake from

birth, whereas Child B has the same Pb intake as Child A for the first two years of life, then a 1-year elevated intake beginning at age 24 months (Figure 4-7, upper panel) that returns to the same intake as Child A at 36 months. The absorption fraction is assumed to be the same for both children. Blood Pb samples 1 and 5 for Child A and B, or 2 and 4 for Child B, will yield similar blood Pb concentrations (~3 or 10 µg/dL, respectively), yet the exposure contexts for these samples are very different. Two samples (e.g., 1 and 2, or 4 and 5), at a minimum, are needed to ascertain if the blood Pb concentration is changing over time. The rate of change can provide information about the magnitude of change in exposure, but not necessarily about the time history of the change (Figure 4-7, lower panel). Time-integrated measurements of Pb concentration may provide a means for accounting for some of these factors and, thereby, provide a better measure of long-term Pb exposure.



Note: Child A and Child B had a constant basal Pb intake (10 µg/day) from birth; Child B experienced an elevated intake of 5.5 µg/day/kg for 1 year beginning at 24 months of age (upper panel). Blood Pb measurements 1 and 5 for Child A and B, or 2 and 4 for Child B, will yield similar blood Pb concentrations (~3 or 10 µg/dL, respectively), yet the exposure scenarios for these samples are very different. As shown in the example of Child C and Child D, two blood Pb measurements can provide information about the magnitude of change in exposure, but not necessarily the temporal history of the change (lower panel). Child C and D had a constant basal Pb intake (10 µg/day) from birth. Child C experienced an elevated intake of 13 µg/day starting at 12 months of age for 1 year, whereas, Child D experienced an elevated intake of 5.5 µg/day starting at 24 months of age for 1 year. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-7 Simulation of temporal relationships between Pb exposure and blood Pb concentration in children.

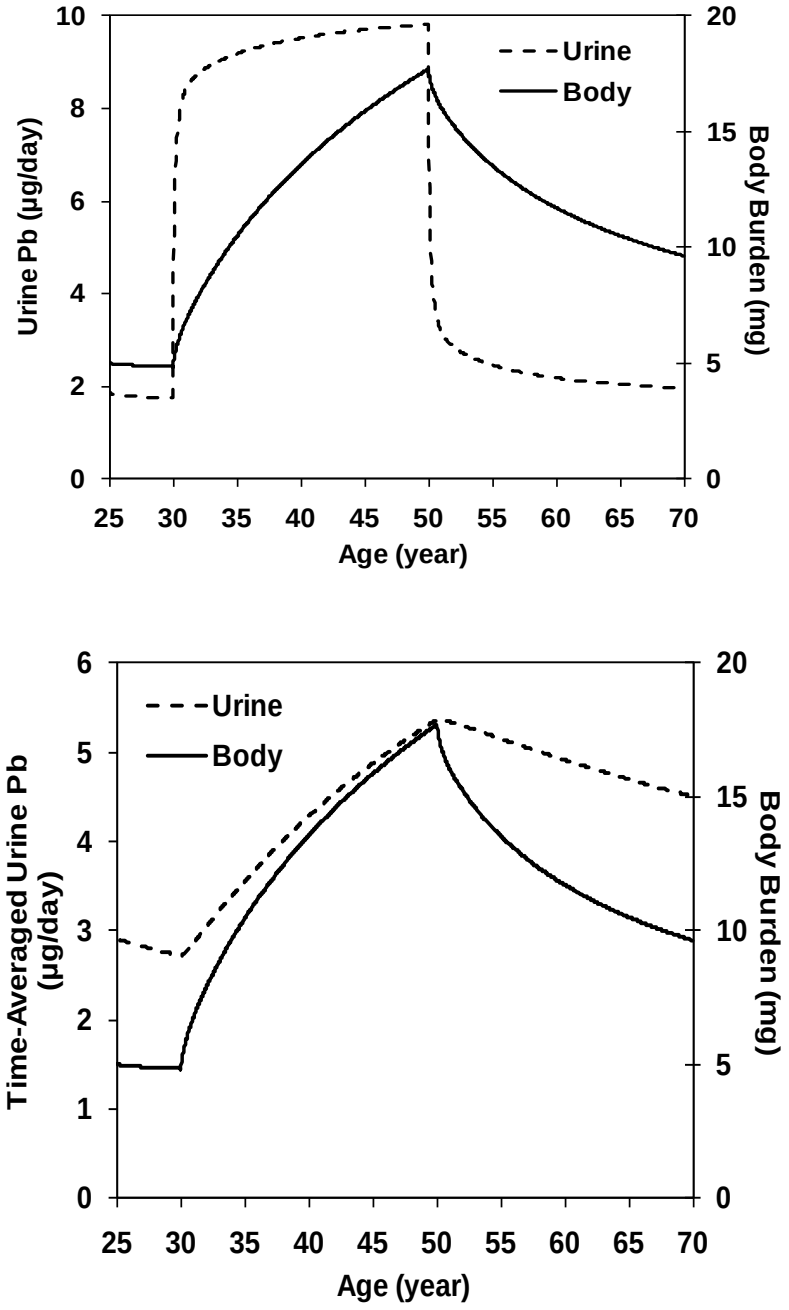
4.3.3 Urine-Pb Measurements

Standard methods that have been reported for urine Pb analysis are, in general, the same as those analyses noted for determination of Pb in blood. Reported detection limits are ~50 µg/L for AAS, 5-10 µg/L for ICP AES, and 4 µg/L for ASV for urine Pb analyses.

The concentration of Pb in urine is a function of the urinary Pb excretion (Section 4.2.3) and the urine flow rate. Urine flow rate requires collection of a timed urine sample, which is often problematic in epidemiologic studies. Collection of untimed ("spot") urine samples, a common alternative to timed samples, requires adjustment of the Pb measurement in urine to account for variation in urine flow (Diamond, 1988). Several approaches to this adjustment have been explored, including adjusting the measured urine Pb concentration by the urine creatinine concentration, urine osmolality, or specific gravity (Fukui et al., 1999; Araki et al., 1990). Urine flow rate can vary by a factor or more than 10, depending on the state of hydration and other factors that affect glomerular filtration rate and renal tubular reabsorption of the glomerular filtrate. All of these factors can be affected by Pb exposure at levels that produce nephrotoxicity (i.e., decreased glomerular filtration rate, impaired renal tubular transport function). Therefore, urine Pb concentration measurements provide little reliable information about exposure (or Pb body burden), unless they can be adjusted to account for unmeasured variability in urine flow rate (Araki et al., 1990).

Urinary Pb concentration reflects, mainly, the concentration of Pb in the blood. As such, urinary concentrations reflect both recent and past exposures to Pb (see Section 4.3.5). A single urinary Pb measurement cannot distinguish between a long-term low level of exposure or a higher acute exposure. Urinary Pb measurements would be expected to correlate with concurrent blood Pb (see Section 4.3.6 for additional discussion of the relationship between blood and urine Pb). Chiang et al. (2008) reported a significant, but relatively weak correlation between urinary Pb levels (µg/dg creatinine) and individual Pb intakes (µg/day) estimated in a group of 10- to 12-year-old children (β: 0.053, $R = 0.320$, $p = 0.02$, $n = 57$). A contributing factor to the relatively weak correlation may have been the temporal displacement between the urine sampling and measurements used to estimate intake, which may have been as long as 6 months for some children.

Thus, a single urine Pb measurement, or a series of measurements taken over short-time span, is likely a relatively poor index of Pb body burden for the same reasons that blood Pb is not a good indicator of body burden. On the other hand, long-term average measurements of urinary Pb can be expected to be a better index of body burden (Figure 4-8).



Note: A change in Pb uptake results in a relatively rapid change in urinary excretion of Pb, to a new quasi-steady state, and a relatively small change in body burden (upper panel). Baseline ingestion was 20 µg/day from age 0 to 30 yrs, then intake increased to 120 µg/day from age 30 to 50 with a subsequent decrease in intake to the baseline of 20 µg/day at age 50. The long-term average urinary Pb excretion more closely tracks the pattern of change in body burden (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-8 Simulation of relationship between urinary Pb excretion and body burden in adults.

4.3.4 Pb in Other Biomarkers

There was extensive discussion in the 2006 Pb AQCD (U.S. EPA, 2006c) regarding the utility of other Pb biomarkers as indicators of exposure or body burden. Due to the fact that most epidemiologic studies continue to use blood Pb or bone Pb, and other potential biomarkers (i.e., teeth, hair, and saliva) have not been established to the same extent as blood or bone Pb, only summaries are provided below.

4.3.4.1 Teeth

Tooth Pb is a minor contributor to the total body burden of Pb. As teeth accumulate Pb, tooth Pb levels are generally considered an estimate of cumulative Pb exposure. The tooth Pb-blood Pb relationship is more complex than the bone Pb-blood Pb relationship because of differences in tooth type, location, and analytical method. Although mobilization of Pb from bone appears well established, this is not the case for Pb in teeth. Conventional wisdom has Pb fixed once it enters the tooth. Although that may be the case for the bulk of enamel, it is not true for the surface of the enamel and dentine (Gulson et al., 1997; Rabinowitz et al., 1993). Limited studies have demonstrated moderate-to-high correlations between tooth Pb levels and blood Pb levels (Rabinowitz, 1995; Rabinowitz et al., 1989).

Teeth are composed of several tissues formed pre- and postnatal. Therefore, if a child's Pb exposure during the years of tooth formation varied widely, different amounts of Pb would be deposited at different rates (Rabinowitz et al., 1993). This difference may allow investigators to elucidate the history of Pb exposure in a child. Robbins et al. (2010) found a significant association between environmental Pb measures that correlated with leaded gasoline use and tooth enamel Pb in permanent teeth. Costa de Almeida et al. (2007) discerned differences between tooth enamel Pb concentration in biopsy samples from children who lived in areas having higher or lower levels of Pb contamination. Gulson and Wilson (1994) advocated the use of sections of enamel and dentine to obtain additional information compared with analysis of the whole tooth (e.g., (Tvinnereim et al., 1997; Fosse et al., 1995). For example, deciduous tooth Pb in the enamel provides information about in utero exposure whereas that in dentine from the same tooth provides information about postnatal exposure until the tooth exfoliates at about 6-7 years of age.

4.3.4.2 Hair

The 2006 Pb AQCD (U.S. EPA, 2006c) discussed applications of hair Pb measurements for assessing Pb body burden or exposure and noted methodological limitations (e.g., external contamination) and lack of a strong empirical basis for relating hair Pb levels to body burden or exposure. No new methodological or conceptual advances regarding hair Pb measurements have occurred since 2006, and widespread application of hair Pb measurements in epidemiologic studies has not occurred.

Pb is incorporated into human hair and hair roots (Bos et al., 1985; Rabinowitz et al., 1976) and has been explored as a noninvasive approach for estimating Pb body burden (Wilhelm et al., 2002; Gerhardsson et al., 1995; Wilhelm et al., 1989). Hair Pb measurements are subject to error from contamination of the surface with environmental Pb and contaminants in artificial hair treatments (i.e., dyeing, bleaching, permanents) and are a relatively poor predictor of blood Pb concentrations, particularly at blood Pb levels less than 10-12 µg/dL (Rodrigues et al., 2008; Campbell and Toribara, 2001; Esteban et al., 1999; Drasch et al., 1997). Temporal relationships between Pb exposure and hair Pb levels, and kinetics of deposition and retention of Pb in hair have not been evaluated. Although hair Pb measurements have been used in some epidemiologic studies (Shah et al., 2011; U.S. EPA, 2006b), an empirical basis for interpreting hair Pb measurements in terms of body burden or exposure has not been firmly established.

4.3.4.3 Saliva

A growing body of literature on the utility of measurements of salivary Pb has developed since the completion of the 2006 Pb AQCD (U.S. EPA, 2006b). Earlier reports suggested a relatively strong correlation between salivary Pb concentration and blood Pb concentration (Omokhodion and Crockford, 1991; Brodeur et al., 1983; P'an, 1981); however, more recent assessments have shown relatively weak or inconsistent associations (Costa de Almeida et al., 2011; Costa de Almeida et al., 2010; Costa de Almeida et al., 2009; Barbosa et al., 2006a; Nriagu et al., 2006). The differences in these outcomes may reflect differences in blood Pb concentrations, exposure history and/or dental health (i.e., transfer of Pb between dentin and saliva) and possibly methods for determining Pb in saliva. Barbosa et al. (2006a) found a significant but relatively weak correlation (log[blood PB] versus log[saliva Pb], r = 0.277, p = 0.008) in a sample of adults, ages 18-60 years (n = 88). The correlation was similar for salivary and plasma Pb. Nriagu et al. (2006) found also found a relatively weak association ($R^{2 =}$ 0.026) between blood Pb (µg/dL) and salivary Pb (µg/L) in a sample of adults who resided in Detroit, MI (n = 904). Costa de Almeida et al. (2009) found a significant correlation between salivary

and blood Pb concentrations in children in a Pb-contaminated region in Sao Paulo State, Brazil (r = 0.76. p = 0.04, n = 7) prior to site remediation; however, the correlation degenerated (r = 0.03, p = 0.94, n = 9) following remediation. Nevertheless, salivary Pb concentrations in the group of children who lived in the contaminated area were significantly elevated compared to a reference population. It is possible, that salivary Pb measurements may be a useful non-invasive biomarker for detecting elevated Pb exposure; however, it is not clear based on currently available data, if salivary Pb measurements would be a more reliable measure of exposure than blood Pb measurements.

4.3.4.4 Serum δ-ALA and ALAD

The association between blood Pb and blood ALAD activity and serum δ-aminolevulinic acid (δ-ALA) levels was recognized decades ago as having potential use as a biomarker of Pb exposure (Mitchell et al., 1977; Hernberg et al., 1970). More recently reference values for blood ALAD activity ratio (the ratio of ALAD activity in the blood sample to that measured after fully activating the enzyme in the sample) have been reported (Gultepe et al., 2009). Inhibition of erythrocyte ALAD by Pb results in a rise in the plasma concentration of the ALAD substrate δ-ALA. The δ-ALA biomarker can be measured in serum and has been used as a surrogate for Pb measurements in studies in which whole blood samples or adequately prepared plasma or serum samples were not available for Pb measurements (Opler et al., 2008; Opler et al., 2004).

4.3.5 Relationship between Pb in Blood and Pb in Bone

The kinetics of elimination of Pb from the body reflects the existence of multiple pools of Pb in the body that have different elimination kinetics. The dominant washout phase of Pb from the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days (Leggett, 1993; Rabinowitz et al., 1976). Studies of a limited number of adults (four individuals with hip or knee replacement, a married couple, and 10 female Australian immigrants) in which the Pb exposure was from historical environmental sources have found that bone Pb stores can contribute 40-70% to blood Pb (Smith et al., 1996; Gulson et al., 1995a; Manton, 1985). Bone Pb burdens in adults are slowly lost by diffusion (heteroionic exchange) as well as by resorption (O'Flaherty, 1995). Half-times for the release of Pb in bone are dependent on age and intensity of exposure. Bone compartments are much more labile in infants and children than in adults as reflected by half-times for movement of Pb from bone into the plasma (e.g., cortical $t_{1/2}$ = 0.23 years

at birth, 1.2 years at 5 years of age, 3.7 years at 15 years of age, and 23 years in adults; trabecular $t_{1/2}$ = 0.23 years at birth, 1.0 years at 5 years of age, 2.0 years at 15 years of age, and 3.9 years in adults) (Leggett, 1993). Slow transfer rates for the movement of Pb from nonexchangeable bone pools to the plasma are the dominant transfer process determining long-term accumulation and elimination of bone Pb burden.

When blood Pb concentrations are monitored in individuals over periods of years following a cessation or decrease in exposure, the decrease in blood Pb concentration exhibits complex kinetics that can be disaggregated into components having faster and slower rates. The slower rates of clearance of Pb from the blood over months and years following the cessation or reduction in exposures is thought to primarily reflect elimination of Pb stores in bone. Nilsson et al. (1991) reported a tri-exponential decay in the blood Pb concentrations of 14 individuals having a median occupational exposure period of 26 years. Thirteen of these 14 individuals had been temporarily removed from work because of excessive exposures (blood levels ≥ 70 μg/dL or high urinary δ-aminolevulinic acid levels). Representing 22% of blood Pb, the fast compartment had a clearance half time of 34 days. The intermediate compartment, 27% of blood Pb, had a clearance half time of 1.12 year. And, the slow compartment, 50% of blood Pb, had a clearance half time of 13 years. The authors attributed the fast, intermediate, and slow compartment clearance to elimination of Pb from blood and some soft tissues, from trabecular bone, and cortical bone, respectively. Rentschler et al. (2012) also observed a slow terminal phase of Pb elimination from blood in five adults who had Pb poisoning due to either occupational or non-occupational exposures that ranged from approximately 1 month to 12 years and resulted in blood Pb concentrations of 70-110 μg/dL. In this study, the blood Pb monitoring period extended from 1 to 74 days following cessation of exposure to approximately 800 days following the diagnosis of poisoning; however, it was not of sufficient duration to estimate the terminal half-time. When the terminal half-time estimated by Nilsson et al. (1991) was used (13 years) to fit data for these Pb poisoning cases to a two-component exponential decay model, the initial faster phase represented approximately 80% of the blood Pb and the half-time was estimated to range from 60 to 120 days. The relatively longer fast phase half-time reported by Rentschler et al. (2012) compared to Nilsson et al. (1991) may reflect the relatively high blood Pb concentrations in these poisoning cases that resulted in temporary anemia and subsequent reestablishment of a normal erythrocyte levels. Also, the use of a two-compartment model, with an assumed slow half-time of 13 years, as well as uncertainty about the actual time of cessation of exposure may have prevented discerning a third, faster elimination compartment in these data.

Children who have been removed from a relatively brief exposure to elevated environmental Pb also exhibit faster slow-phase kinetics than children removed from exposures that lasted several years, with half-times of 10 and 20-38 months, respectively (Manton et al., 2000). Rothenberg et al. (1998) also showed that exposures in the first 6 months of life could contribute to elevated blood Pb levels through at least 3 years relative to children with lower early life exposures, despite similar environmental exposures at later time points. In both adults and children, the longer half-times measured under the latter conditions reflect the contribution of bone Pb stores to blood Pb following a change in exposure.

The longer half-life of Pb in bone compared to blood Pb, allows a more cumulative measure of long-term Pb exposure. Pb in adult bone can serve to maintain blood Pb levels long after external exposure has ceased (Fleming et al., 1997; Inskip et al., 1996; Smith et al., 1996; Kehoe, 1987; O'Flaherty et al., 1982), even for exposures that occurred during childhood (McNeill et al., 2000). The more widespread use of in vivo XRF Pb measurements in bone and indirect measurements of bone processes with stable Pb isotopes have enhanced the use of bone Pb as a biomarker of Pb body burden.

Several studies have found a stronger relationship between patella Pb and blood Pb than tibia Pb and blood Pb (Park et al., 2009c; Hu et al., 1998; Hernandez-Avila et al., 1996; Hu et al., 1996a). Hu et al. (1998) suggest that trabecular bone is the predominant bone type providing Pb back into circulation under steady-state and pathologic conditions. The stronger relationship between blood Pb and trabecular Pb compared with cortical bone is probably associated with the larger surface area of trabecular bone allowing for more Pb to bind via ion exchange mechanisms and more rapid turnover making it more sensitive to changing patterns of exposure.

Relationships between Pb in blood and bone in children and adults are discussed in greater detail below (Sections 4.3.5.1, and 4.3.5.2). In these discussions, simulations based on a biokinetics model are shown to illustrate general patterns in the relationships between bone Pb and blood Pb that can be predicted based on the current understanding of Pb biokinetics in children and adults. However, these simulations reflect assumptions in the model and may not accurately represent the observed blood Pb kinetics in individuals or variability in blood Pb kinetics observed in specific populations. The simulations include two metrics of blood Pb, the blood Pb concentration at each time point in the simulation and the time-integrated blood Pb for the period preceding each time point in the simulation (also referred to as the cumulative blood Pb index [CBLI]). The time-integrated blood Pb metric has been used to estimate long-term average and cumulative absorbed Pb doses in epidemiologic studies (e.g., Nie et al., 2011b; Healey et

al., 2008; Hu et al., 2007a; Chuang et al., 2000; McNeill et al., 2000; Fleming et al., 1997; Roels et al., 1995; Gerhardsson et al., 1993; Armstrong et al., 1992).

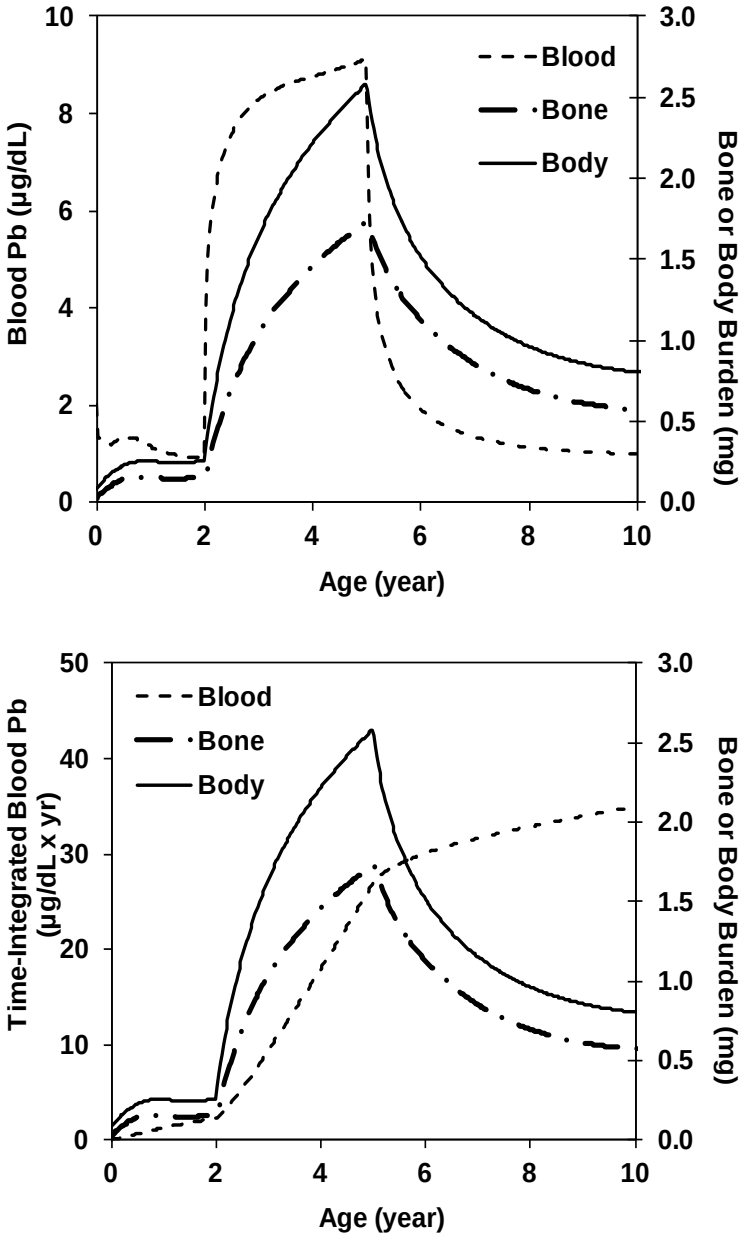
4.3.5.1 Children

As mentioned in Section 4.2.2.2, bone growth in children will contribute to accumulation of Pb in bone, which will comprise most of the Pb body burden. As a result, Pb in bone will more closely reflect Pb body burden than blood Pb. However, changes in blood Pb concentration in children (i.e., associated with changing exposures) are thought to more closely parallel changes in total body burden. Figure 4-9 shows a biokinetics model simulation of the temporal profile of Pb in blood and bone in a child who experiences a period of constant Pb intake (from age 2-5) via ingestion (µg Pb/day) followed by an abrupt decline in intake. The figure illustrates several important general concepts about the relationship between Pb in blood and bone. While blood Pb approaches a quasi-steady state after a period of a few months with a constant rate of Pb intake (as demonstrated by the vertical dashed line), Pb continues to accumulate in bone with continued Pb intake after the quasi-steady state is achieved in blood. The model also predicts that the rate of release of Pb from bone after a reduction in exposure is faster than in adults. This difference has been attributed to accelerated growth-related bone mineral turnover in children, which is the primary mechanism for release of Pb that has been incorporated into the bone mineral matrix.

Empirical evidence in support of this conclusion comes from longitudinal studies in which relatively high correlations were found between concurrent ($r = 0.75$) or average lifetime (obtained at 6-month intervals from birth to age 10 or 12) blood Pb concentrations ($r = 0.85$) and tibia bone Pb concentrations (measured by XRF) in a sample of children in which the group mean concurrent blood Pb concentration exceeded 20 µg/dL; the correlations was much weaker ($r < 0.15$) among the group of children with a mean concurrent blood Pb concentration <10 µg/dL (Wasserman et al., 2003).

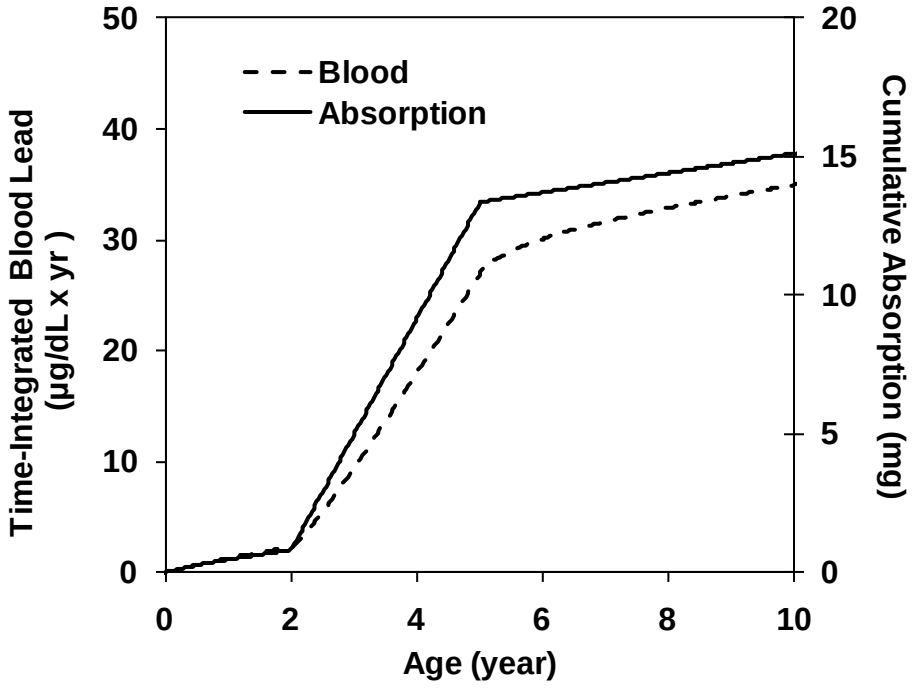
Time-integrated blood Pb metrics display rates of change in response to the exposure event that more closely approximate the slower kinetics of bone Pb and body burden, than the kinetics of blood Pb concentration, with notable differences (Figure 4-9). The time-integrated blood PB concentration is a cumulative function and increases throughout childhood; however, the slope of the increase is higher during the exposure event than prior to or following the event. Following cessation of the enhanced exposure period, the time-integrated blood Pb and body burden diverge. This result is expected, as the time-integrated blood Pb curve is a cumulative function which cannot decrease over time and bone Pb levels will decrease with reduction in exposure.

The time-integrated blood Pb concentration will be a better reflection of the total amount of Pb that has been absorbed, than the body burden at any given time. The time-integrated blood Pb concentration will also reflect cumulative Pb absorption, and cumulative exposure if the absorption fraction is constant. This is illustrated in the hypothetical simulations of an exposure event experienced by a child (Figure 4-10). This pattern is similar for adults.



Note: Blood Pb concentration is thought to parallel body burden more closely in children than in adults, due to more rapid turnover of bone and bone-Pb stores in children (upper panel). Baseline Pb intake is 3.2 µg/day from birth until age 2, followed by a period of increased intake (38.2 µg/day) from age 2 until age 5, with a return to baseline intake of 3.2 µg/day at age 5. The time-integrated blood Pb concentration increases over time (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-9 Simulation of relationship between blood Pb concentration and body burden in children, with an elevated constant Pb intake from age 2 to 5 years.



Note: The simulations include a 3-year period of elevated constant Pb intake during ages 2-5 years. Baseline Pb intake is 3.2 µg/day from birth until age 2, followed by a period of increased intake (38.2 µg/day) from age 2 until age 5, with a return to baseline intake of 3.2 µg/day at age 5. The time-integrated blood Pb concentration closely parallels cumulative Pb absorption. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-10 Simulation of relationship between time-integrated blood Pb concentration and cumulative Pb absorption in children.

4.3.5.2 Adults

In adults, where a relatively large fraction of the body burden residing in bone has a slower turnover compared to blood, a constant Pb uptake (or constant intake and fractional absorption) gives rise to a quasi-steady state blood Pb concentration, while the body burden continues to increase over a much longer period, largely as a consequence of continued accumulation of Pb in bone. This pattern is illustrated in Figure 4-11 that depicts a hypothetical simulation of an exposure consisting of a 20-year period of daily ingestion of Pb in an adult. The exposure shown in the simulations gives rise to a relatively rapid increase in blood Pb concentration from a baseline of approximately 2 µg/dL, to a new quasi-steady state of approximately 9 µg/dL, achieved in ~75-100 days (i.e., approximately 3-4 times the blood elimination half-life). In contrast, the body burden exhibits a steady increase across the full exposure period of 70 yr. Following cessation of the enhanced exposure period, blood Pb concentration declines relatively

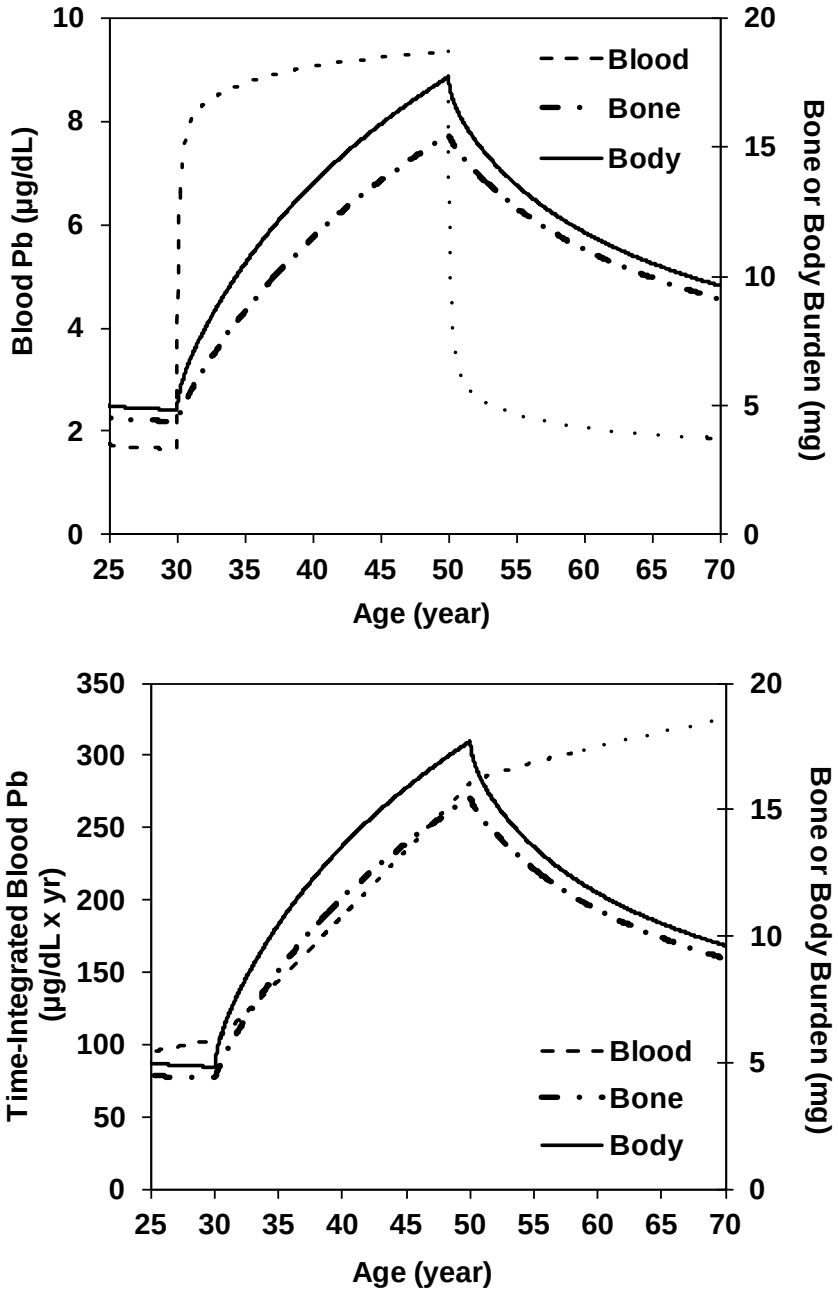
rapidly compared to the slower decline in body burden. Careful examination of the simulation shown in Figure 4-11 reveals that the accumulation and elimination phases of blood Pb kinetics are not symmetrical; elimination is slower than accumulation as a result of the gradual release of bone Pb stores to blood. This response, known as the prolonged terminal elimination phase of Pb from blood, has been observed in retired Pb workers and in workers who continued to work after improved industrial hygiene standards reduced their exposures. In the adult simulation shown in Figure 4-11, following cessation of the enhanced exposure period at age 50, the blood Pb concentration is reduced by half in approximately 75 days. Following this relatively short elimination period, the half-time of the subsequent 4-year period is approximately 14 years; however, the half-time increases to approximately 50 years during the period 5-20 years after the reduction in exposure.

These model predictions are consistent with the slow elimination of Pb from blood and elimination half-times of several decades for bone Pb (e.g., 16-98 years) that have been estimated from observations made on Pb workers (Wilker et al., 2011; Fleming et al., 1997; Gerhardsson et al., 1995). Based on this hypothetical simulation, a blood Pb concentration measured 1 year following cessation of a period of increased Pb uptake would be elevated by only a relatively small amount over the baseline measured prior to the exposure (3 µg/dL versus the 2 µg/dL), whereas, the body burden would remain elevated. These simulations in Figure 4-11 illustrate how a single blood Pb concentration measurement, or a series of measurements taken over a short-time span, could be a relatively poor index of Pb body burden. The simulation shown in Figure 4-11 represents an exposure that resulted in a quasi-steady state blood Pb concentration of approximately 10 µg/dL. Exposures that achieve higher blood Pb concentrations, more indicative of poisoning or historic occupational exposures will result in a more prolonged elevation of blood Pb concentration following cessation of the enhanced exposure period. Figure 4-12 shows a model simulation of an adult exposed to Pb that results in a quasi-steady state blood Pb concentration of approximately 90 µg/dL. In this case, the blood Pb concentration remains substantially elevated 1 year following the exposure event (42 µg/dL versus 2 µg/dL) and 20 years following the exposure event (11 µg/dL).

One important potential implication of the profoundly different kinetics of Pb in blood and bone is that, for a constant Pb exposure, Pb in bone will increase with increasing duration of exposure and, therefore, with age. In contrast, blood Pb concentration will achieve a quasi-steady state. As a result, the relationship between blood Pb and bone Pb will diverge with increasing exposure duration and age. This divergence can impart different degrees of age-confounding when either blood Pb or bone Pb is used as an internal dose metric in dose-response models. In a review of epidemiologic studies that evaluated the associations between blood Pb, bone Pb and cognitive function, the

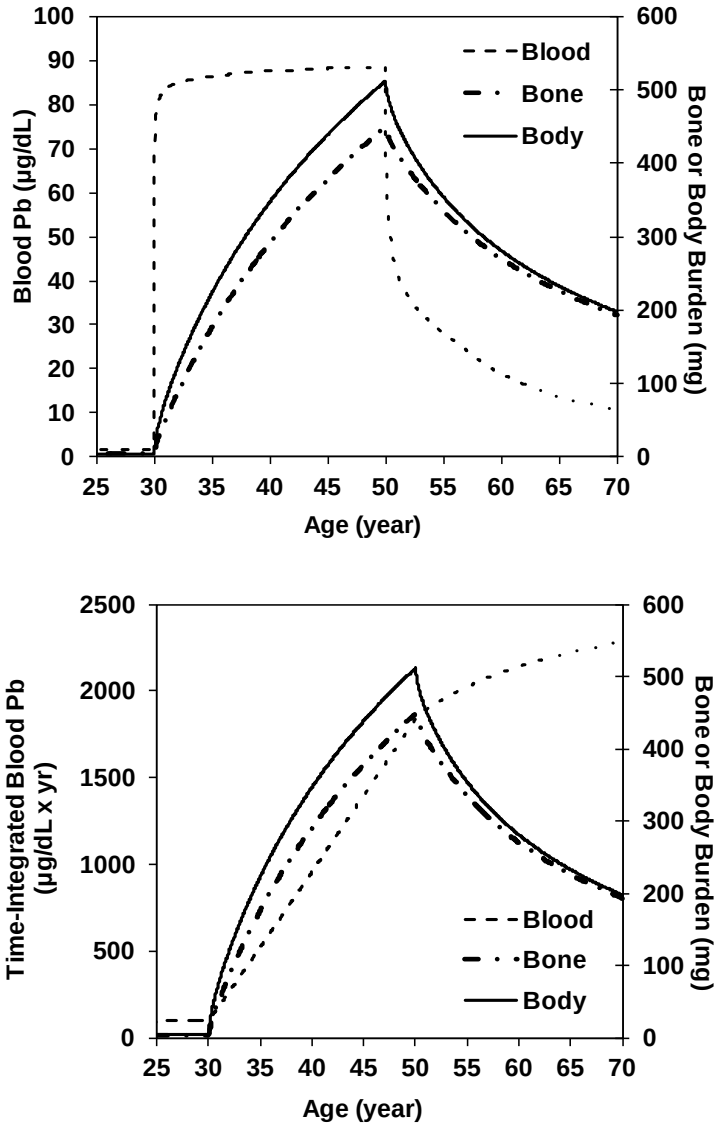
association was stronger for bone Pb than blood Pb (particularly for longitudinal studies) for older individuals with environmental Pb exposures and low blood Pb levels (Shih et al., 2007). In contrast, occupational workers with high current Pb exposures had the strongest associations for blood Pb levels with cognitive function, thus providing evidence for this divergence (Shih et al., 2007).

The aforementioned expectation for an increase in bone Pb and body burden with age applies to scenarios of constant exposure but not necessarily to real world populations in which individual and population exposures have changed over time. Longitudinal studies of blood and bone Pb trends have not always found strong dependence on age (Nie et al., 2009; Kim et al., 1997). Kim et al. (1997) found that bone Pb levels increased with increasing age in elderly adults (age 52-83) years), only when the data were analyzed cross-sectionally. When analyzed longitudinally, the trend for individual patella Pb was a 23% decrease over a 3-year period (approximate $t_{1/2}$ of 8 years), whereas tibia Pb levels did not change with over the same period. Therefore, although older individuals tended to have higher bone Pb levels, the 3-year temporal trend for individuals was a loss of Pb from the more labile Pb stores in trabecular bone. Nie et al. (2011a) observed that longitudinal observations of blood and bone Pb in elderly adults did not show a significant age effect on the association between blood Pb and bone Pb (patella and tibia), when the sample population (n=776) was stratified into age tertiles (mean age 62, 69 or 77 years). Nie et al. (2009) did find that regressed function bone Pb and appeared to level off at bone Pb levels >20 µg/g bone mineral.



Note: A constant baseline intake of 20 µg/day from age 0-30 results in a quasi-steady state blood Pb concentration and body burden. An increase in Pb intake to 120 µg/day from age 30 to 50 gives rise to a relatively rapid increase in blood Pb, to a new quasi-steady state, and a slower increase in body burden (upper panel). At age 50, intake returns to the baseline of 20 µg/day. Following the long period of elevated Pb intake, there is a rapid decline in blood Pb from 9 to 3 µg/dL over the first year and a more gradual decline in blood Pb to less than 2 µg/dL by age 60. The time-integrated blood Pb concentration increases over the lifetime, with a greater rate of increase during periods of higher Pb uptake (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-11 Simulation of relationship between blood Pb concentration, bone Pb and body burden in adults with relatively low Pb intake.



Note: A constant baseline intake of 20 µg/day from age 0-30 results in a quasi-steady state blood Pb concentration and body burden. A increase in Pb intake to 6020 µg/day from age 30 to 50 gives rise to a relatively rapid increase in blood Pb, to a new quasi-steady state, and a slower increase in body burden (upper panel). At age 50, intake returns to the baseline of 20 µg/day. Following the long period of high Pb intake, there is a rapid decline in blood Pb from 90 to 40 µg/dL over the first a year followed by a more gradual decline in blood Pb to 20 µg/dL by age 60 and 10 µg/dL at age 70. The time-integrated blood Pb concentration increases over the lifetime, with a greater rate of increase during periods of higher Pb uptake (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-12 Simulation of relationship between blood Pb concentration, bone Pb and body burden in adults with relatively high Pb intake.

Tibia bone Pb is correlated with time-integrated blood Pb concentration (i.e., CBLI). McNeill et al. (2000) compared tibia Pb levels and cumulative blood Pb indices in a population of 19- to 29-year-olds who had been highly exposed to Pb in childhood from the Bunker Hill, Idaho smelter. They concluded that Pb from exposure in early childhood had persisted in the bone matrix until adulthood. The bone Pb/CBLI slopes from various studies range from 0.022 to 0.067 μg/g bone mineral per μg-year/dL (Healey et al., 2008; Hu et al., 2007a). Because the CBLI is a cumulative function which cannot decrease over time, CBLI and bone Pb would be expected to diverge following cessation of exposure, as bone Pb levels decrease. This divergence was observed as a lower bone Pb/CBLI slope in retired Pb workers compared to active workers and in worker populations whose exposures declined over time as a result of improved industrial hygiene (Fleming et al., 1997; Gerhardsson et al., 1993).

Although differences in kinetics of blood and bone Pb degrade the predictive value of blood Pb as a metric of Pb body burden, within a population that has similar exposure histories and age demographics, blood and bone Pb may show relatively strong associations. A recent analysis of a subset of data from the Normative Aging Study (an all male cohort) showed that cross-sectional measurements of blood Pb concentration accounted for approximately 9% (tibia) to 13% (patella) of the variability in bone Pb levels. Inclusion of age in the regression model accounted for an additional 7-10% of the variability in bone Pb (Park et al., 2009c).

Mobilization of Pb from Bone in Adulthood

In addition to changes in exposure (e.g., declines in exposure discussed in prior sections), there are physiological processes during different life circumstances that can increase the contribution of bone Pb to blood Pb. These life circumstances include times of physiological stress associated with enhanced bone remodeling such as during pregnancy and lactation (Hertz-Picciotto et al., 2000; Silbergeld, 1991; Manton, 1985), menopause or in the elderly (Silbergeld et al., 1988), extended bed rest (Markowitz and Weinberger, 1990), hyperparathyroidism (Kessler et al., 1999) and severe weight loss (Riedt et al., 2009).

During pregnancy, bone Pb can serve as a Pb source as maternal bone is resorbed for the production of the fetal skeleton (Gulson et al., 2003; Gulson et al., 1999; Franklin et al., 1997; Gulson et al., 1997). Increased blood Pb during pregnancy has been demonstrated in numerous studies and these changes have been characterized as a “U-shaped” pattern of lower blood Pb concentrations during the second trimester compared to the first and third trimesters (Lamadrid-Figueroa et al., 2006; Gulson et al., 2004a; Hertz-Picciotto et al., 2000; Gulson et al., 1997; Lagerkvist et al., 1996; Schuhmacher et al., 1996;

Rothenberg et al., 1994a). The U-shaped relationship reflects the relatively higher impact of hemodilution in the second trimester versus the rate of bone Pb resorption accompanying Ca^{2+} releases for establishing the fetal skeleton. In the third trimester, fetal skeletal growth on calcium demand is greater, and Pb released from maternal skeleton offsets hemodilution. Gulson et al. (1998b) reported that, during pregnancy, blood Pb concentrations in the first immigrant Australian cohort (n = 15) increased by an average of about 20% compared to non-pregnant migrant controls (n = 7). Skeletal contribution to blood Pb, based on the isotopic composition for the immigrant subjects, increased in an approximately linear manner during pregnancy. The mean increases for each individual during pregnancy varied from 26% to 99%. Interestingly, the percent change in blood Pb concentration was significantly greater during the post-pregnancy period than during the second and third trimesters. This is consistent with Hansen et al. (2011b) that demonstrated the greatest blood Pb levels at 6 weeks postpartum compared to the second trimester in 211 Norwegian women. Increased calcium demands of lactation (relative to pregnancy) may contribute to the greater change in blood Pb observed post pregnancy compared to the second and third trimesters. The contribution of skeletal Pb to blood Pb during the post-pregnancy period remained essentially constant at the increased level of Pb mobilization.

Gulson et al. (2004a) observed that calcium supplementation was found to delay increased mobilization of Pb from bone during pregnancy and halved the flux of Pb release from bone during late pregnancy and postpartum. In another study, women whose daily Ca^{2+} intake was 850 mg per day showed lower amounts of bone resorption during late pregnancy and postpartum than those whose intake was 560 mg calcium per day (Manton et al., 2003). Similarly, calcium supplementation (1,200 mg/day) in pregnant Mexican women resulted in an 11% reduction in blood Pb level compared to placebo and a 24% average reduction for the most compliant women (Ettinger et al., 2009). When considering baseline blood Pb levels in women who were more compliant in taking calcium supplementation, the reductions were similar for those <5 µg/dL and those ≥ 5 µg/dL (14% and 17%, respectively). This result is in contrast to a study of women who had blood Pb concentrations <5 µg/dL, where calcium supplementation had no effect on blood Pb concentrations (Gulson et al., 2006b). These investigators attributed their results to changes in bone resorption with decoupling of trabecular and cortical bone sites.

Miranda et al. (2010) studied blood Pb level among pregnant women aged 18-44 years old. The older age segments in the study presumably had greater historic Pb exposures and associated stored Pb than the younger age segments. Compared with the blood Pb levels of a reference group in the 25-29 years old age category, pregnant women ≥ 30 years old had significant odds of having higher blood Pb levels (aged 30-34:

OR = 2.39, p <0.001; aged 35-39: OR = 2.98, p <0.001; aged 40-44: OR = 7.69, p <0.001). Similarly, younger women had less chance of having higher blood Pb levels compared with the reference group (aged 18-19: OR = 0.60, p = 0.179; aged 20-24: OR = 0.54, p = 0.015). These findings indicate that maternal blood Pb levels are more likely the result of Pb mobilization of bone stores from historic exposures as opposed to contemporaneous exposures.

Blood Pb levels increase during lactation due to alterations in the endogenous bone Pb release rate. After adjusting for patella Pb concentration, an increase in blood Pb levels of 12.7% (95% CI: 6.2, 19.6) was observed for women who practiced partial lactation and an increase of 18.6% (95% CI: 7.1, 31.4) for women who practiced exclusive lactation compared to those who stopped lactation (Tellez-Rojo et al., 2002). In another Mexico City study, Ettinger et al. (2006; 2004b) concluded that an interquartile increase in patella Pb was associated with a 14% increase in breast milk Pb, whereas for tibia Pb the increase was ~5%. Breast milk:maternal blood Pb concentration ratios are generally <0.1, although values of 0.9 have been reported (Koyashiki et al., 2010; Ettinger et al., 2006; Gulson et al., 1998a). Dietary intake of polyunsaturated fatty acids (PUFA) has been shown to weaken the association between Pb levels in patella and breast milk, perhaps indicating decreased transfer of Pb from bone to breast milk with PUFA consumption (Arora et al., 2008). Breast milk as a source of infant Pb exposure was also discussed in Section 4.1.3.3 on dietary Pb exposure.

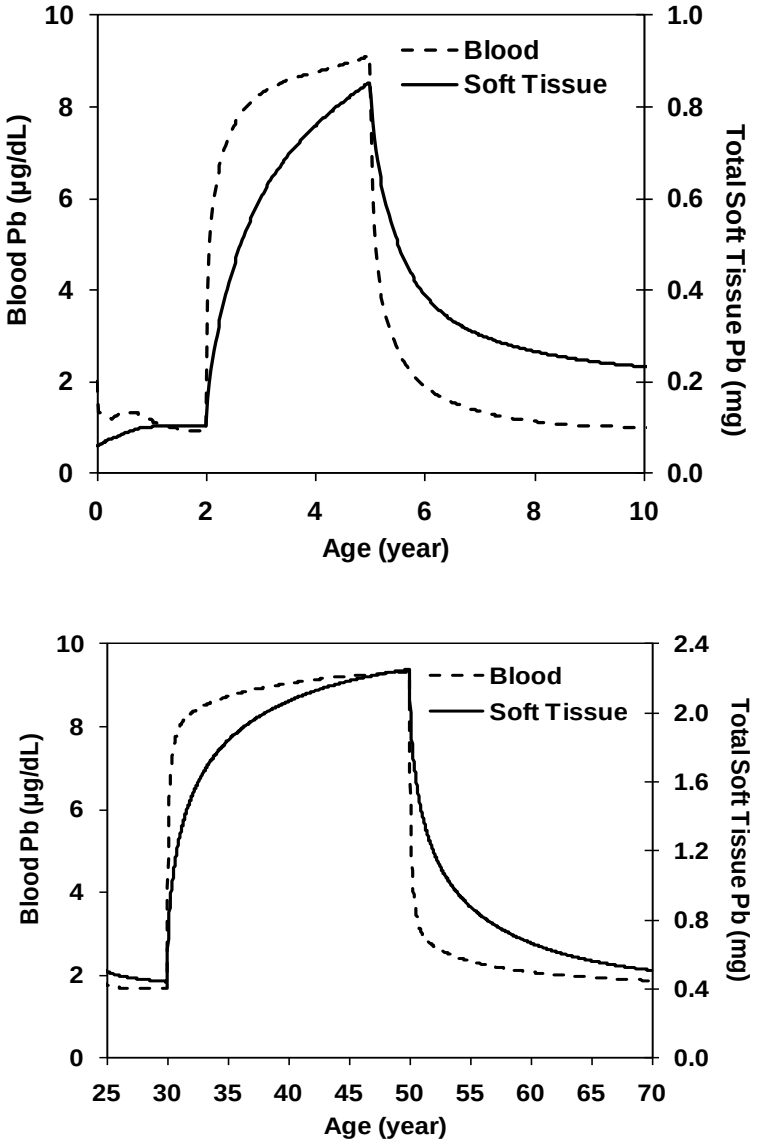
The Pb content in some bones (i.e., mid femur and pelvic bone) plateau at middle age and then decreases at older ages (Drasch et al., 1987). This decrease is most pronounced in females and may be due to osteoporosis and release of Pb from resorbed bone to blood (Gulson et al., 2002). Two studies indicate that the endogenous release rate in postmenopausal women ranges from 0.13-0.14 µg/dL in blood per µg/g bone and is nearly double the rate found in premenopausal women (0.07-0.08 µg/dL per µg/g bone) (Popovic et al., 2005; Garrido Latorre et al., 2003). An analysis of data on blood Pb concentrations and markers of bone formation (serum alkaline phosphatase) and resorption (urinary cross-linked N-telopeptides, NTx) in a sample of U.S. found that blood Pb concentrations were higher in women (pre- or post-menopausal) who exhibited the highest bone formation or resorption activities (Jackson et al., 2010). Calcium or vitamin D supplementation decreased the blood Pb concentrations in the highest bone formation and resorption tertiles of the population of post-menopausal women. Significant associations between increasing NTx and increasing blood Pb levels (i.e., increased intercept of regression model relating the change in blood Pb per change in bone Pb) has also been observed in elderly males (Nie et al., 2009).

Studies of the effect of hormone replacement therapy on bone Pb mobilization have yielded conflicting results (Popovic et al., 2005; Berkowitz et al., 2004; Garrido Latorre et al., 2003; Korrick et al., 2002; Webber et al., 1995). In women with severe weight loss (28% of BMI in 6 months) sufficient to increase bone turnover, increased blood Pb levels of approximately 2.1 µg/dL (250%) were reported, and these blood Pb increases were associated with biomarkers of increased bone turnover (e.g., urinary pyridinoline cross-links) (Riedt et al., 2009).

4.3.6 Relationship between Pb in Blood and Pb in Soft Tissues

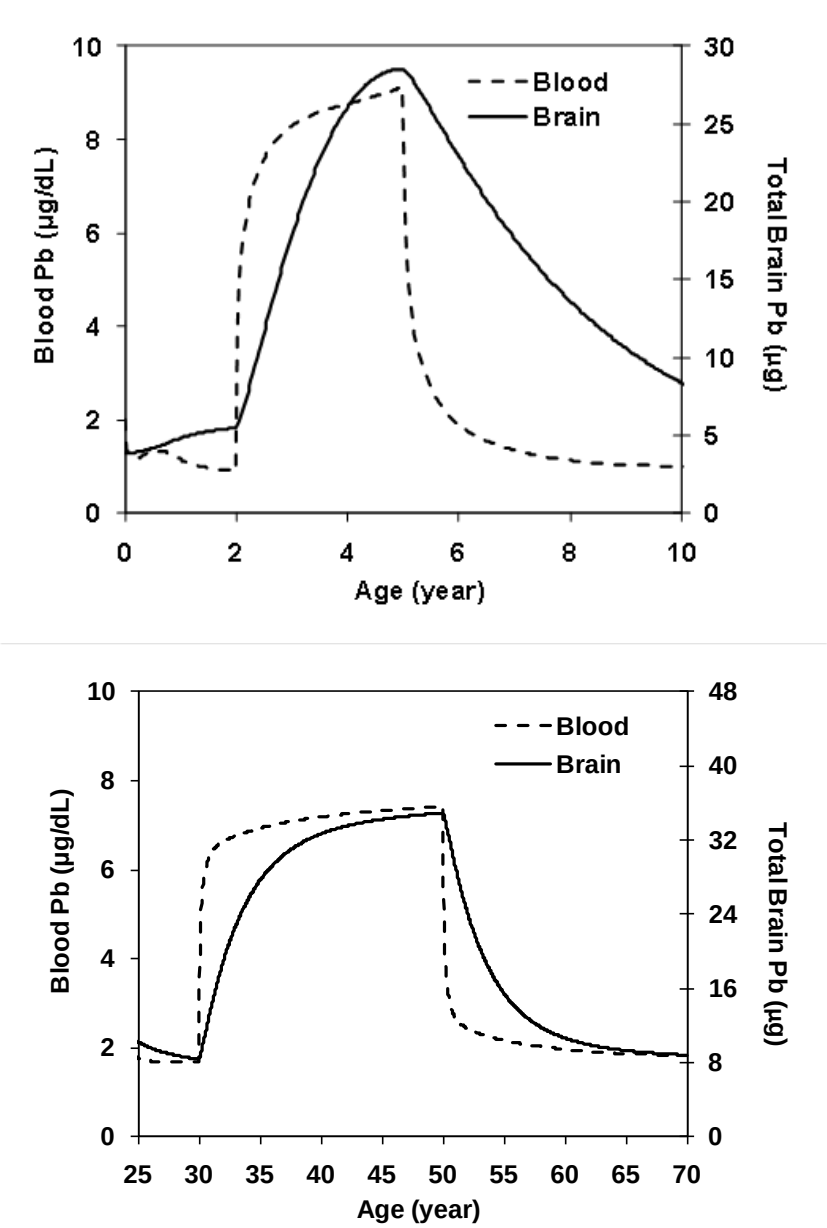
Figure 4-13 shows simulations of blood and soft tissues Pb (including brain) for the same exposure scenarios previously displayed. Pb uptake and elimination in soft tissues is much faster than bone. As a result, following cessation of a period of elevated exposure, Pb in soft tissues is more quickly returned to blood. The terminal elimination phase from soft tissue mimics that of blood, and it is similarly influenced by the contribution of bone Pb returned to blood and being redistributed to soft tissue.

Information on Pb levels in human brain is limited to autopsy data. These data indicate brain/blood Pb ratios of approximately 0.5 in infancy which remain relatively constant over the lifetime (range 0.3 to 1.1) (Barry, 1981, 1975). The simulation of brain Pb shown in Figure 4-14 reflects general concepts derived from observations made in non-human primates, dogs and rodents. These observations suggest that peak Pb levels in the brain are reached 6 months following a bolus exposure and within two months approximately 80% of steady state brain Pb levels are reached (Leggett, 1993). There is a relatively slow elimination of Pb from brain ($t_{1/2} \approx 2$ years) compared to other soft tissues (Leggett, 1993). This slow elimination rate is reflected in the slower elimination phase kinetics is shown in Figure 4-14. Although in this model, brain Pb to blood Pb transfer half-times are assumed to be the same in children and adults, uptake kinetics are assumed to be faster during infancy and childhood, which achieves a higher fraction of the soft tissue burden in brain, consistent with higher brain/body mass relationships. The uptake half times predicted by Leggett (1993) vary from 0.9 to 3.7 days, depending on age. Brain Pb kinetics represented in the simulations are simple outcomes of modeling assumptions and cannot currently be verified with available observations in humans.



Note: For the child simulation (upper panel), baseline Pb intake is 3.2 µg/day from birth until age 2, followed by a period of increased intake to 38.2 µg/day from age 2 until 5, with a return to baseline intake at age 5. For the adult simulation (lower panel), baseline intake is 20 µg/day from age 0-30, followed by a 20-year period of increased intake to 120 µg/day from age 30 to 50, with a return to baseline intake at age 50. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

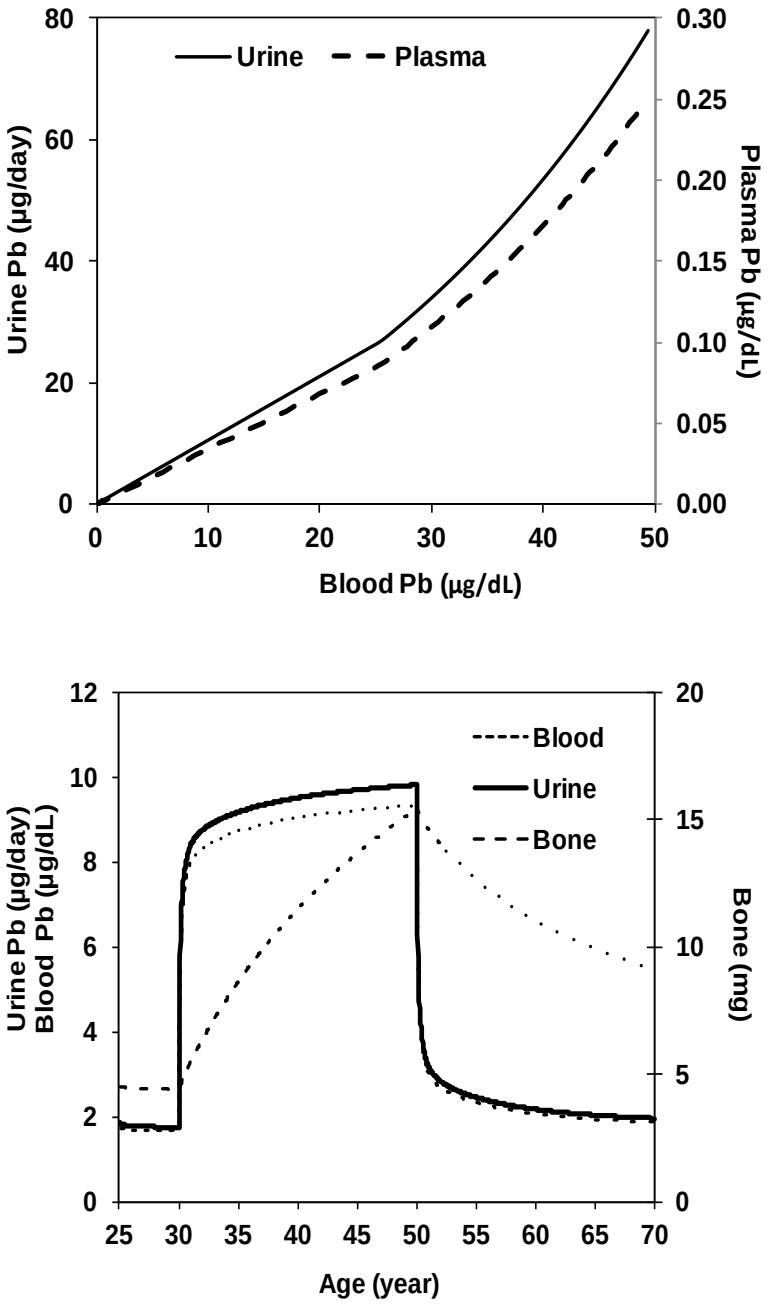
Figure 4-13 Simulation of blood and soft tissue (including brain) Pb in children and adults who experience a period of increased Pb intake.



Note: For the child simulation (upper panel), baseline Pb intake is 3.2 µg/day from birth until age 2, followed by a period of increased intake to 38.2 µg/day from age 2 until 5, with a return to baseline intake at age 5. For the adult simulation (lower panel), baseline intake is 20 µg/day from age 0-30, followed by a 20-year period of increased intake to 120 µg/day from age 30 to 50, with a return to baseline intake at age 50. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-14 Simulation of blood and brain Pb in children and adults who experience a period of increased Pb intake.

Urinary filtering and excretion of Pb is associated with plasma Pb concentrations. Given the curvilinear relationship between blood Pb and plasma Pb, a secondary expectation is for a curvilinear relationship between blood Pb and urinary Pb excretion that may become evident only at relatively high blood Pb concentrations (e.g., >25 µg/dL). Figure 4-15 shows these relationships predicted from the model. In this case, the exposure scenario shown is for an adult (age 40 years) at a quasi-steady state blood Pb concentration; the same relationships hold for children. At lower blood Pb concentrations (<25 µg/dL), urinary Pb excretion is predicted to closely parallel plasma Pb concentration for any given blood Pb level (Figure 4-15, top panel). It follows from this that, similar to blood Pb, urinary Pb will respond much more rapidly to an abrupt change in Pb exposure than will bone Pb. One important implication of this relationship is that, as described previously for blood Pb, the relationships between urinary Pb and bone Pb will diverge with increasing exposure duration and age, even if exposure remains constant. Furthermore, following an abrupt cessation of exposure, urine Pb will quickly decrease while bone Pb will remain elevated (Figure 4-15, lower panel).



Note: Upper panel, model simulations are for a 40-year old having a constant intake from birth of between 1 and 1,000 µg/day. For the lower panel, baseline intake is 20 µg/day from age 0-30, followed by a 20-year period of increased intake to 120 µg/day from age 30 to 50, with a return to baseline intake at age 50. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-15 Relationship between Pb in urine, plasma, blood and bone.

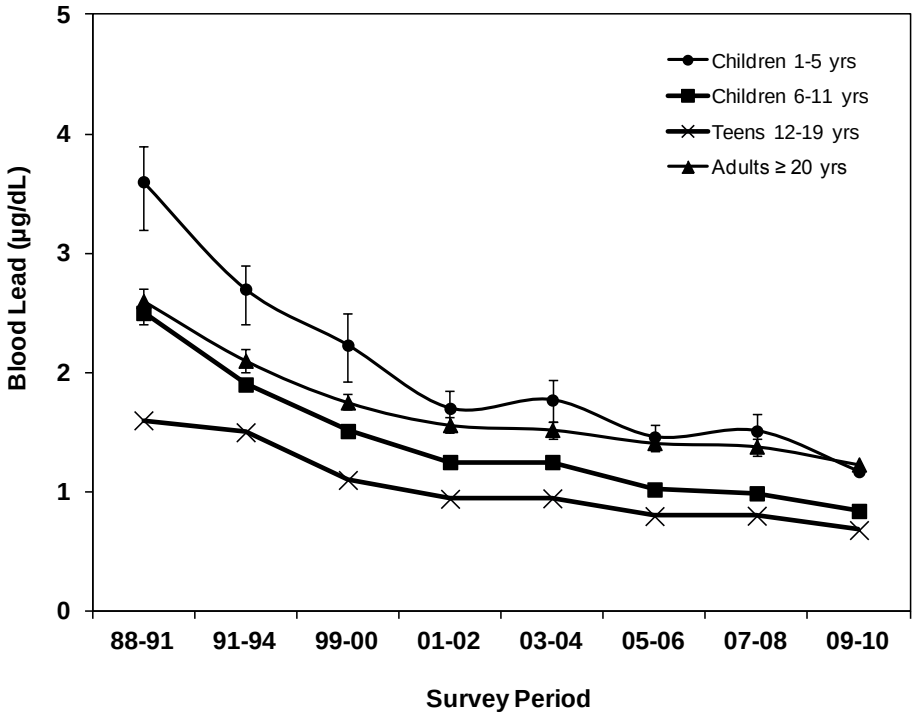
4.4 Studies of Pb Biomarker Levels

4.4.1 Pb in Blood

Overall, trends in blood Pb levels have been decreasing among U.S. residents over the past 35 years. Blood Pb concentrations in the U.S. general population have been monitored in the NHANES. Analyses of these data show a progressive downward trend in blood Pb concentrations during the period 1976-2010, with the most dramatic declines coincident with the phase out of leaded gasoline and reductions in point source Pb emissions described in Section 3.2 (Pirkle et al., 1998; Brody et al., 1994; Pirkle et al., 1994; Schwartz and Pitcher, 1989). The temporal trend for the period 1988-2010 is shown in Figure 4-16. Summary statistics from the most recent publicly available data (1999-2010) are presented in Table 4-8 (CDC, 2011a). The geometric mean Pb concentration among children 1-5 years of age, based on the sample collected during the period 2009-2010, was 1.17 µg/dL (95% CI: 1.08, 1.26), which was decreased from 2007-2008 (1.51 µg/dL, 95% CI: 1.37, 1.66). Figure 4-17 uses NHANES data to illustrate temporal trends in the distribution of blood Pb levels among U.S. children aged 1-5 years. For 2005-2010, the 95th percentile of blood Pb levels for children aged 1-5 years was less than 5 µg/dL. The geometric mean blood Pb concentration among adults ≥ 20 years of age was 1.23 µg/dL (95% CI: 1.19, 1.28) for the sample collected during the period 2009-2010 (CDC, 2011a). Based on these same data, the geometric mean for all males (aged ≥ 1 year) was 1.31 µg/dL (95% CI: 1.25, 1.36), and for females (aged ≥ 1 year) was 0.97 µg/dL (95% CI: 0.93, 1.01).

There has been a steep decline in mean blood Pb levels from 1975 through 2010 among all birth cohorts from 1975 to 2010 (Figure 4-18). For all cohorts, blood Pb generally decreases with age during childhood until adolescence; following adolescence (in the early 20s), blood Pb generally levels off or even increases with age. It is possible that bone growth in young people and occupational exposure for adults influences the shape of these curves. For the 1960 to 1970 birth cohort, the mean blood Pb is the highest of the cohorts in the 1970s, but beginning in 1993 the mean blood Pb is one of the lowest of the cohorts. This interaction between time and cohort may be due to the faster release of Pb from bone in younger people (Rabinowitz, 1991). This interaction is also apparent for some of the other more recently born cohorts. In comparison, the slopes of blood Pb over time are nearly parallel among the cohorts born before 1960. This suggests that the time-cohort-interaction diminishes among older people. Also, the leveling of the blood Pb in the 2000s could be due to aging of the birth cohort and consequent slowing of their Pb release from bone.

When race/ethnicity groups were compared for years 1999-2004, geometric means (GM) of blood Pb levels in children were highest in the ethnicity category non-Hispanic black (GM 2.8, 95% CI: 2.5, 3.0) compared to the categories Mexican-American (GM 1.9, 95% CI: 1.7, 2.0) and non-Hispanic white (GM 1.7, 95% CI: 1.6, 1.8) (Jones et al., 2009a). Figure 4-19 demonstrates the change in percent of children (aged 1-5 years) with various blood Pb levels by race/ethnicity between the survey during 1988-1991 and that during 1999-2004. When these data for children aged 1-5 years were aggregated for all survey years from 1988 to 2004, residence in older housing, poverty, age, and being non-Hispanic black were significant predictors of higher Pb levels (Jones et al., 2009a).



Note: Shown are geometric means and 95% CIs based on data from NHANES III Phase 1 (Brody et al., 1994; Pirkle et al., 1994); NHANES III Phase 2 (Pirkle et al., 1998); and NHANES IV (CDC, 2011a). Data for adults during the period 1988-1994 are for ages 20-49 years, and ≥ 20 years for the period 1999-2008.

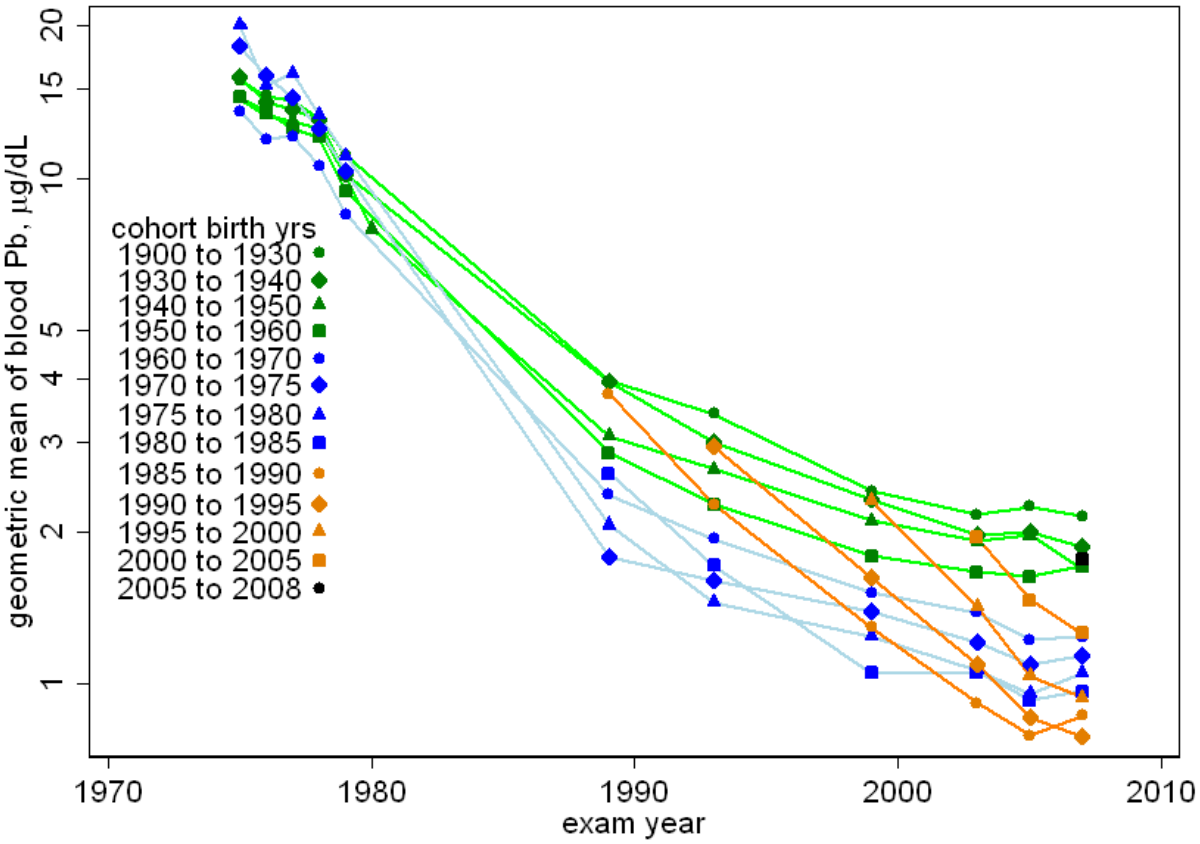
Figure 4-17 Box plots of blood Pb levels among U.S. children (1-5 years old at baseline) from the NHANES survey, 1988-2010.



Note: The means of logged blood Pb were weighted to represent national averages. Data were from the publicly available NHANES II, NHANES II for 1988-1991 and 1992-1994, and the continuous NHANES in 1999-2000, 2003-2004, 2005-2006, 2007-2008. Continuous NHANES data from 2001-2002 and 2009-2010 are not included because there were only 551 blood Pb samples in each of those data sets. The year plotted for exam year was the reported exam year for NHANES II, the middle year of each of the phases of NHANES III, and the second year of each of the continuous NHANES.

Figure 4-19 Percent distribution of blood Pb levels by race/ethnicity among U.S. children (1-5 years) from the NHANES survey, 1988-1991 (top) and 1999-2004 (bottom).

In agreement with the 1986 AQCD (U.S. EPA, 1986a), several studies have shown seasonal variation in blood Pb concentrations in children (e.g., Havlena et al., 2009; Gulson et al., 2008; Kemp et al., 2007; Laidlaw et al., 2005; Haley and Talbot, 2004; Johnson and Bretsch, 2002; Yiin et al., 2000; Johnson et al., 1996), with elevated concentrations during the warm season and lower levels in the cold season. Seasonal dynamics of blood Pb concentrations in children appear to be caused at least in part by seasonal patterns in access of children to soils and soil properties (e.g., moisture content) that may contribute to seasonal variation in entrainment of soil and dust Pb into breathing zone air (Laidlaw et al., 2012; Laidlaw et al., 2005; Johnson and Bretsch, 2002). Seasonal variation in blood Pb concentrations occur with strong associations with soil Pb concentrations (Johnson and Bretsch, 2002). Laidlaw et al. (2012) observed that air Pb in the $PM_{2.5}$ fraction and $PM_{2.5}$ attributed to soil were elevated in the warm season compared with the cold season. Yiin et al. (2000) found that geometric mean for blood Pb, floor Pb loading and concentration, and carpet dust loading were statistically significantly higher in the cold season compared with the hot season. However, regression of blood Pb on floor and windowsill dust with and without adjustment for the hot, warm, and cool seasons showed no statistically significant effect of the seasons directly on blood Pb. Meteorological factors appear to contribute to blood Pb seasonality. Laidlaw et al. (2005) analyzed the temporal relationships between child blood Pb concentrations and various atmospheric variables in three cities (Indianapolis, IN: 1999-2002; Syracuse, NY: 1994-1998; New Orleans, LA: 1998-2003). Blood Pb data was obtained from public health screening programs conducted in the three cities. Blood Pb samples were dominated by children <5 years of age and age distribution varied across the three cities. The temporal variation in blood Pb concentrations in each city was predicted by multivariate regression models that included the following significant variables: PM_{10}, wind speed, air temperature, and soil moisture; as well as dummy variables accounting for temporal displacement of the effects of each independent variable on blood Pb. Laidlaw et al. (2005) reported R^2 values for the regression models, but did not report the actual regression coefficients. The R^2 values were as follows: Indianapolis 0.87 ($p = 0.004$); Syracuse 0.61 ($p = 0.0012$); New Orleans 0.59 ($p < 0.00001$).

Studies have examined the change in blood Pb with changes in potential Pb sources. Gulson et al. (2004b) observed that children living near a Zn-Pb smelter in Australia had blood Pb levels ranging from 10 to 42 µg/dL, with 55-100% of Pb attributed to the smelter based on isotope ratio analysis. Rubio-Andrade et al. (2011) followed a cohort of 6-8 year old children living within 3.5 km of a Mexican smelter at 0, 6, 12, and 60 months after environmental intervention including removal of 100,000 kg of Pb-containing dust from roads and homes using high efficiency vacuums. Soil Pb was concurrently obtained but not reported at 6, 12, or 60 months. Median blood Pb level at initiation of the study was 10.1 µg/dL for the 598 initial participants (average age: 7.2 y),

and median soil Pb was 3,300 mg/kg at the start of the study. After 60 months, median blood Pb level was 4.4 µg/dL for the remaining 232 participants (average age: 12.2 y), and median soil Pb concentration was 370 mg/kg at that time. Bonnard and McKone (2009) modeled blood Pb of French children ages 21-74 months living within a village containing a Pb smelter and estimated blood Pb levels of 3.2-10.9 µg/dL. Lanphear et al. (1998) noted that the probability of children having blood Pb ≥ 10 µg/dL increases both with exterior soil Pb content and interior Pb dust loading. Mielke et al. (2011b) noted significant increases in percentages of children younger than 7-years old with blood Pb level ≥ 10 µg/dL for those living in inner city New Orleans housing developments (22.9%) compared with children living in communities located on the city outskirts (9.1%). At the same time, median soil Pb was significantly higher in the inner city (438 mg/kg) compared with the city outskirts (117 mg/kg).

For infants <1 year old, very little data are available on blood Pb levels. Simon et al. (2007) followed a cohort of 13 children living near an Australian smelter from birth through 36 months. In general, except for children born with low blood Pb levels of ~1 to 2 µg/dL, immediately after birth blood Pb levels fell for 1-2 months to approximately 47% of birth blood Pb level. After this initial fall, all infants' blood Pb levels rose with age until approximately 12 months old for children living in a high risk area and until approximately 18 months for children living in a low risk area (Simon et al., 2007). Median blood Pb level among the children was 1.9 µg/dL at 2 months and increased to 13.6 µg/dL at 16 months. Geometric mean hand-Pb loading of the child and the mother were significant contributors to the area under the curve for infant blood Pb, with 46% (infant hand loading) and 60% (mother hand loading) of the variance being explained by these variables, respectively; geometric mean of the mothers' blood Pb explained 46% of the variance (Simon et al., 2007). Across all the data, there was a good correlation between child blood Pb level and child hand Pb loading ($R^2 = 0.70$). In another study (Carbone et al., 1998), blood Pb levels of 15 infants aged 6-12 months were statistically significantly lower than their neonatal cord blood Pb levels (2.24 µg/dL versus 4.87 µg/dL). Additionally, 3 infants born with blood Pb levels of greater than 7 µg/dL were followed for a week, there was a dramatic drop in the blood Pb of from an average of 7.6 µg/dL on Day 1 to 2.4 µg/dL on Day 7 (Carbone et al., 1998).

Pb body burden has been reported among individuals known to consume wild game hunted with Pb shot. For example, fifty men from Nuuk, Greenland participated in a study in which they recorded their diet and produced blood samples (Johansen et al., 2006). Men who regularly ate hunted sea birds had an average blood Pb concentration of 12.8 µg/dL, in contrast with those who did not and had an average blood Pb concentration of 1.5 µg/dL. Umbilical cord blood was collected from a cohort of Inuit newborns from northern Quebec, where the Inuit population consumes game killed with

Pb shot (Lévesque et al., 2003). The geometric mean cord blood Pb level was 0.19 µmol/L [3.9 µg/dL], with a range of 0.01-1.31 µmol/L [0.2-27 µg/dL]; the Canadian level of concern for cord blood Pb is 0.48 µmol/L [10 µg/dL]. The authors contrasted the finding that 7% of Inuit newborns had cord blood Pb concentration ≥ 0.48 µmol/L [10 µg/dL] in contrast with 0.16% of the Caucasian population in southern Quebec.

Recent studies have sought to characterize human exposure to Pb from piston-engine aircraft emissions. Section 3.2.2.1 describes a study by Carr et al. (2011) in which Pb concentrations, both modeled and monitored, extended beyond airport property. Miranda et al. (2011) used GIS to study the association between blood Pb level and distance from airports in six North Carolina Counties. They observed that the trend in blood Pb level decreases monotonically with distance class from the airports, with subjects within 500 meters of the airports having significantly increased blood Pb levels ($\beta = 0.043$, 95% CI: (0.006,0.080), $p < 0.05$) compared with the general population for a given county after controlling for proportion of black, Hispanic, percent receiving public assistance, and household median income at the census block group level and including dummy variables for season during which the children were screened for blood Pb. In this study, children living within 500 meters of an airport had blood Pb levels that were, on average, 4.4% higher than those at distance. Note that the authors did not include Pb emissions in their model.

Trends in blood Pb levels have been accompanied by changes in Pb isotope ratios for blood Pb. Isotopic ratios, described in Sections 3.2 and 3.3 as a tool for source apportionment, have been used to associate blood Pb measurements with anthropogenic sources of Pb in the environment. Changes in Pb isotopic ratios in blood samples reflect the changing influence of sources of Pb following the phase-out of tetraethyl Pb antiknock agents in automotive gasoline and changes in Pb usage in paints and other industrial and consumer products (Gulson et al., 2008; Ranft et al., 2008; Gulson et al., 2006a; Ranft et al., 2006). Gulson et al. (2006a) illustrated how a linear increase in the isotopic ratio $^{206}Pb/^{204}Pb$ occurred in concert with a decrease in blood Pb levels among selected study populations in Australia during the period 1990-2000 (Figure 4-20). Gulson et al. (2006a) point out that the isotopic signature of $^{206}Pb/^{204}Pb$ derived from Australian mines (median ~16.8) differs from that of European and Asian mines, where $^{206}Pb/^{204}Pb$ varies between ~17.4 and ~18.1. Liang et al. (2010) also examined the trends in blood Pb level over the period 1990 to 2006 in Shanghai and saw a reduction corresponding to the phase out of Pb in gasoline. A plot of $^{208}Pb/^{206}Pb$ to $^{207}Pb/^{206}Pb$ for blood and environmental samples showed overlap between the isotopic signature for coal combustion ash and that measured in blood. This result suggests a growing influence of Pb from coal ash in Shanghai in the absence of Pb in automobile emissions. Oulhote et al. (2011) examined Pb isotope ratios in blood Pb samples of 125 French children aged 6

mo-6 yr. The study found that Pb isotope ratios could be used to attribute Pb exposure to one source for 32% of children and to eliminate an unlikely source of Pb exposure in 30% of children.

4.4.2 Pb in Bone

An extensive national database (i.e., NHANES) is available for blood Pb concentrations in children and adults, as described in Section 4.4.1. Bone Pb concentrations are less well characterized. Table 4-9 and Table 4-10 are compilations of data from epidemiologic studies that provided bone Pb concentrations by K-XRF and/or variability in concentrations among individuals without reported occupational exposure and those with occupational exposures, respectively. In non-occupationally exposed individuals, typical group mean tibia bone Pb concentrations ranged from 10 to 30 μg/g. Patella bone Pb levels are typically higher than tibia bone Pb levels in the studies considered (Table 4-9). For example, in the Normative Aging Study, patella bone Pb concentrations were approximately 32 μg/g, whereas tibia bone Pb concentrations were about 22 μg/g. Occupationally exposed individuals generally had greater bone Pb concentrations than seen in control groups (i.e., unexposed). Bone Pb data in Table 4-10 for occupationally exposed individuals were also generally higher compared to non-occupationally exposed individuals (Table 4-9).

Table 4-9 Epidemiologic studies that provide bone Pb measurements for non-occupationally exposed populations.

4.4.3 Pb in Urine

Urine Pb concentrations in the U.S. general population have been monitored in the NHANES. Data from the most recent survey (CDC, 2011a) are shown in Table 4-11. The geometric mean for the entire sample for the period 2007-2008 (n = 2,627) was 0.52 µg/g creatinine (95% CI: 0.48, 0.55). The geometric means for males (n = 1,327) and females (n = 1,300) were 0.50 µg/g creatinine (95% CI: 0.47, 0.53) and 0.53 µg/g creatinine (95% CI: 0.49, 0.57), respectively.

Table 4-11 Urine Pb concentrations in the U.S. population.

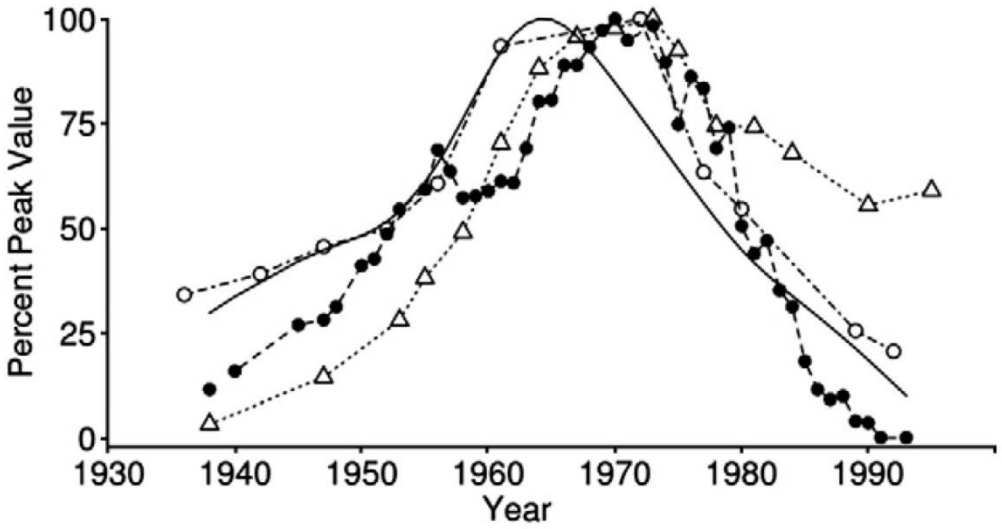
4.4.4 Pb in Teeth

The influence of historical Pb exposures was recently studied by Robbins et al. (2010). Tooth enamel samples from 127 subjects born between 1936 and 1993 were analyzed for Pb concentration and Pb isotope ratios of the tooth enamel and compared with those parameters for sediment cores and estimates of Pb emissions from gasoline during the years when 50% enamel formation was estimated to occur. They found that the log-transform of tooth enamel concentration was significantly predicted by the log-transform of Lake Erie sediment core data obtained by Graney et al. (1995) ($p < 0.00001$) and by the log-transform of U.S. consumption of Pb in gasoline ($p < 0.00001$); see Figure 4-21. Additionally, Robbins et al. (2010) found that $^{207}Pb/^{206}Pb$ was significantly predicted by the $^{207}Pb/^{206}Pb$ observed in the Lake Erie sediment cores obtained by Graney et al. (1995) ($p < 0.0001$) and for this study ($p < 0.0002$).



Note: The lines and symbols on the plot represent Pb in study participant teeth (solid line), newly obtained Pb sediment Lake Erie cores (open triangles), Pb in previously obtained Lake Erie sediment [open circles, Graney et al. (1995)], and U.S. gasoline usage (closed circles). All values are normalized by the peak observation for that parameter.

Source: Reprinted with permission of Elsevier Publishing, Robbins et al. (2010).

Figure 4-21 Comparison of relative temporal changes in tooth enamel Pb concentration.

Several Brazillian studies have found increased levels of Pb in teeth in areas where Pb sources are present. For example, Costa de Almeida et al. (2007) reported Pb concentration in tooth enamel among 4-6 year old kindergarteners in São Paulo, Brazil to be significantly higher for children living near a Pb-acid battery processing plant in the Baruru neighborhood compared with 4-6 year old children in other parts of the city (non-exposed median: 206 mg/kg, n = 247; exposed median: 786 mg/kg, n = 26; $p < 0.0001$). Subsequent analysis revealed that 55% of 4-6 year old children from Baruru had tooth enamel Pb concentrations greater than 600 mg/kg, forming a significant comparison with other neighborhoods having 0-33% of 4-6 year old children with tooth enamel Pb greater than 600 mg/kg ($p < 0.0001$) (de Almeida et al., 2008). The authors did not describe controlling for additional factors, such as socioeconomics or housing conditions. Arruda-Neto et al. (2009) studied Pb in tooth samples among São Paulo children to compare exposures of children age 4-12 years, living near a dam with heavy metal sediments with those of children ages 4-13 years, living in a control area thought to have few exposures. They observed a significant comparison (near dam: avg 1.28 ± 0.11 mg/kg, n = 50; control region: avg 0.91 mg/kg, n = 24). In a related study of Pb measures in teeth among the general population ages 7-60 years, Arruda-Neto et al.(2010) observed that 10-year old children had the highest teeth Pb concentrations, which were 115% of the teeth Pb concentrations in 7-year olds. Twenty-year old subjects had teeth Pb concentrations at roughly 50% of the 7-year olds' teeth Pb concentrations. Tooth Pb

concentrations stayed fairly constant throughout adulthood but then dropped to just above 30% among 65-year old subjects. Note that the authors did not clarify if average or median values were presented, nor did they adjust for potentially confounding factors.

4.5 Empirical Models of Pb Exposure-Blood Pb Relationships

Multivariate regression models, commonly used in epidemiology, provide estimates of the contribution of variance in the internal dose metric to various determinants or control variables (e.g., air Pb concentration, surface dust Pb concentration). Structural equation modeling links several regression models together to estimate the influence of determinants on the internal dose metric. Regression models can provide estimates of the rate of change of blood or bone Pb concentration in response to an incremental change in exposure level (i.e., slope factor). One strength of regression models for this purpose is that they are empirically verified within the domain of observation and have quantitative estimates of uncertainty imbedded in the model structure. However, regression models are based on (and require) paired predictor-outcome data, and, therefore, the resulting predictions are confined to the domain of observations and are typically not generalizable to other populations. Regression models also frequently exclude numerous parameters that are known to influence human Pb exposures (e.g., soil and dust ingestion rates) and the relationship between human exposure and tissue Pb levels, parameters which are expected to vary spatially and temporally. Thus, extrapolation of regression models to other spatial or temporal contexts, which is often necessary for regulatory applications of the models, can be problematic.

A variety of factors may potentially affect estimates of blood Pb-air Pb slope factors. Simultaneous changes in other (nonair) sources of Pb exposure can affect the relationship indicated for air Pb. For example, remedial programs (e.g., community and home-based dust control and education) may be responsible for partial blood Pb reduction seen in some studies. The effect of remedial programs may lead to an overestimation of declines in blood Pb due to changes in air Pb and a corresponding positive bias in blood Pb-air Pb slopes. However, model adjustment for remedial programs and other factors (e.g., soil Pb concentrations) may also cause a negative bias in blood Pb-air Pb slopes. A tendency over time for children with lower blood Pb levels to not return for follow-up testing has been reported. The follow-up of children with higher blood Pb levels would likely lead to an underestimation of reductions in blood Pb following reductions in air Pb and cause a negative bias in blood Pb-air Pb slopes. Another factor is the extent to which all the air Pb exposure pathways are captured by the data set and its analysis. For example, some pathways (such as exposure through the diet or surface soils) may respond more slowly to changes in air Pb than others (such as inhalation). Additionally, some studies may include

adjustments for variables that also reflect an influence from air Pb (e.g., SES or soil Pb). Studies may also vary in the ages of subjects, which given age-related changes in blood Pb can also influence estimates. Many studies have utilized TSP measurements of air Pb concentrations. The sampling efficiency of TSP samplers is affected by particle size distribution, wind speed, and wind direction as described in Section 3.4.1. For example, especially for larger particles (aerodynamic diameter of 20 μm or more), TSP sampling efficiency decreases with increasing wind speed. Such effects on TSP sampling efficiency can, in areas where such large particles are a substantial portion of airborne Pb, lead to uncertainties in the comparability of air Pb concentrations between samples within a study and across studies. A uniformly low bias in air Pb concentrations in a study could positively bias estimated blood Pb-air Pb slopes for that study. Moreover, variability in TSP samples is likely to result from temporal variation in wind speed, wind direction, and source strength; see Sections 3.3 and 3.5. Such temporal variability would tend to increase uncertainty and reduce the statistical strength of the relationship between air Pb and blood Pb but may not necessarily affect the slope of this relationship. A number of factors including those described above cause uncertainty in the magnitude of estimated blood Pb-air Pb slope factors and may lead to both positive and negative biases in the estimates from individual studies.

4.5.1 Air Pb-Blood Pb Relationships in Children

The 1986 Pb AQCD (U.S. EPA, 1986a) described epidemiological studies of relationships between air Pb and blood Pb. Of the studies examined, the aggregate blood Pb-air Pb slope factor (when considering both air Pb and Pb in other media derived from air Pb) was estimated to be approximately double the slope estimated from the contribution due to inhaled air alone (U.S. EPA, 1986a).

Much of the pertinent earlier literature (e.g., prior to 1984) on children's blood Pb levels was summarized by Brunekreef (1984). Based on meta-analysis of data from studies of urban or industrial-urban populations in 18 different locations, Brunekreef (1984) estimated the blood Pb-air Pb slope for children to be 0.3485 ln[μg/dL blood Pb] per ln[μg/m^3 air Pb] (R^2 = 0.69; see Figure 4-22). This slope corresponds to an increase of 4.6 μg/dL blood Pb per μg/m^3 air Pb at an air Pb concentration of 1.5 μg/m^3 for all groups included in the analysis. The 1.5 μg/m^3 value is the median of the air Pb concentrations that match the blood Pb concentrations in 96 different child populations in Figure 3 of Brunekreef et al. (1984), taken from the Appendix to the same paper. When the analysis was limited to child populations whose mean blood Pb concentrations were <20 μg/dL (n=43) , the slope was 0.2159 (R^2=0.33), which corresponds to an increase of 4.8 μg/dL blood Pb per μg/m^3 air Pb at the median air concentration (0.54 μg/m^3).

Newer studies that provide estimates for the blood Pb-air Pb slope factor are described in the sections that follow. Those studies that have at least three data points are included, as fewer than that contributes little to the understanding of the shape of the blood Pb-air Pb relationship. A tabular summary of the major outcomes is provided in Table 4-12. In some studies, the blood Pb-air Pb relationship was described with a nonlinear regression function, in which the blood Pb-air Pb slope factor varied with air Pb concentration. Studies also varied with regard to the use of simple or multivariate regression and, for the latter, with regard to variables included. In Table 4-12, with the exception of Ranft et al. (2008), slopes corresponding to a central estimate of the air Pb concentrations are provided, to represent each study. These were calculated by evaluating each regression function at ± 0.01 $\mu g/m^3$ from the central estimate of the air Pb concentration. Air Pb concentration ranges and central estimates varied across studies, making it difficult to interpret comparisons based solely on the central estimates of the slope factors. Therefore, Figure 4-23 depicts the relationship between the blood Pb-air Pb slope factor as a function of air Pb concentration for the range of air Pb concentrations evaluated in those studies that provided the regression equation (the central estimate is also shown). Figure 4-23 provides a more informative picture of the extent to which slope estimates vary (and overlap) within and between studies. The Ranft et al. (2008) study includes a separate term for soil Pb, so the blood Pb-air Pb slope factor presented for that study underestimates the slope factor that would reflect all air-related pathways, since soil Pb encompasses deposited ambient air Pb. A few studies used a log-log model that predict an increase in the blood Pb-air Pb slope factor with decreasing air Pb concentration, and the remainder of the studies used linear models that predict a constant blood Pb-air Pb slope factor across all air Pb concentrations.

Table 4-12 Summary of estimated slopes for blood Pb to air Pb slope factors in humans.

[a] Slope is predicted change in blood Pb (µg/dL per µg/m^3) evaluated at ± 0.01 µg/m^3 from central estimate of air Pb for the study (shown in parentheses), with the exception of Ranft et al. (2008) in which the slope from the paper is provided because the regression equation was not available. The central estimate for Brunekreef (1984) is the median of air Pb concentrations since it was a meta-analysis; for all other studies the mean is presented. For multiple regression models, this is derived based only on air Pb coefficient and intercept. Depending on extent to which other variables modeled also represent air Pb, this method may underestimate the slope attributable to air pathways. In single regression models, the extent to which non-modeled factors, unrelated to air Pb exposures, exert an impact on blood Pb that covaries with air Pb may lead to the slope presented here to over represent the role of air Pb.

[b] ln(PbB) = ln(PbA) x 0.3485 + 2.853

[c] ln(PbB) = ln(PbA) x 0.2159 + 2.620

[d] ln(PbB) = ln(PbA) x 0.24 + 3.17

[e] PbB = PbA x 7.0

[f] Observed blood Pb values not provided; data are for regressed adjusted blood Pb.

[g] PbB = PbA x 8.6

[h] Based on air Pb data for U.S. (1986 Pb AQCD) as a surrogate for Chicago.

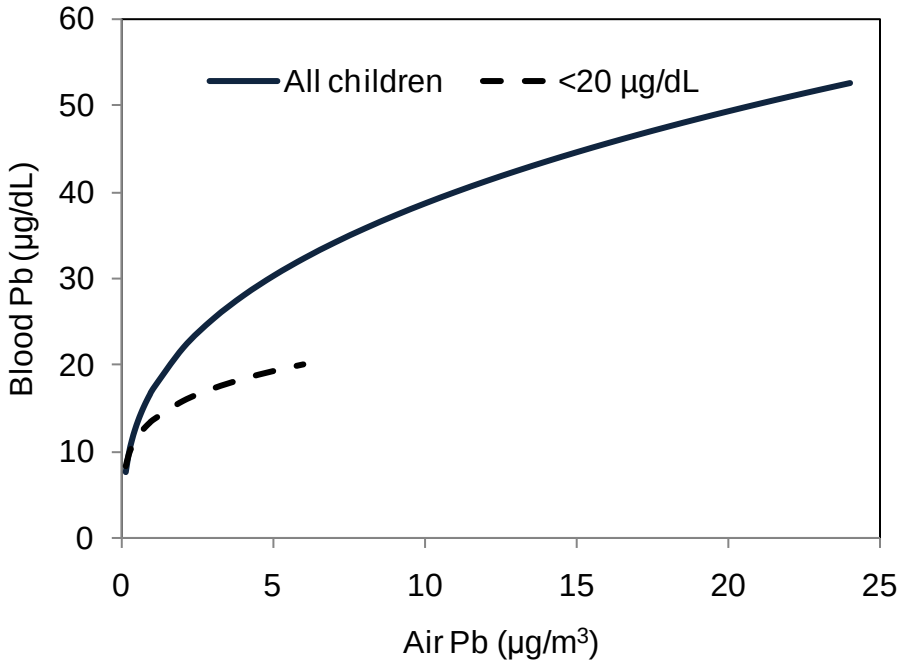
[i] PbB = Pb A x 3.6

[j] Study that considered air Pb and soil Pb where the air Pb-blood Pb relationship was adjusted for soil Pb.

[k] Slope provided in paper with background blood Pb level of 1.5 and 3 µg/dL, respectively, and GMR of 2.55 for ambient air.

[l] PbB = PbA x 9.63

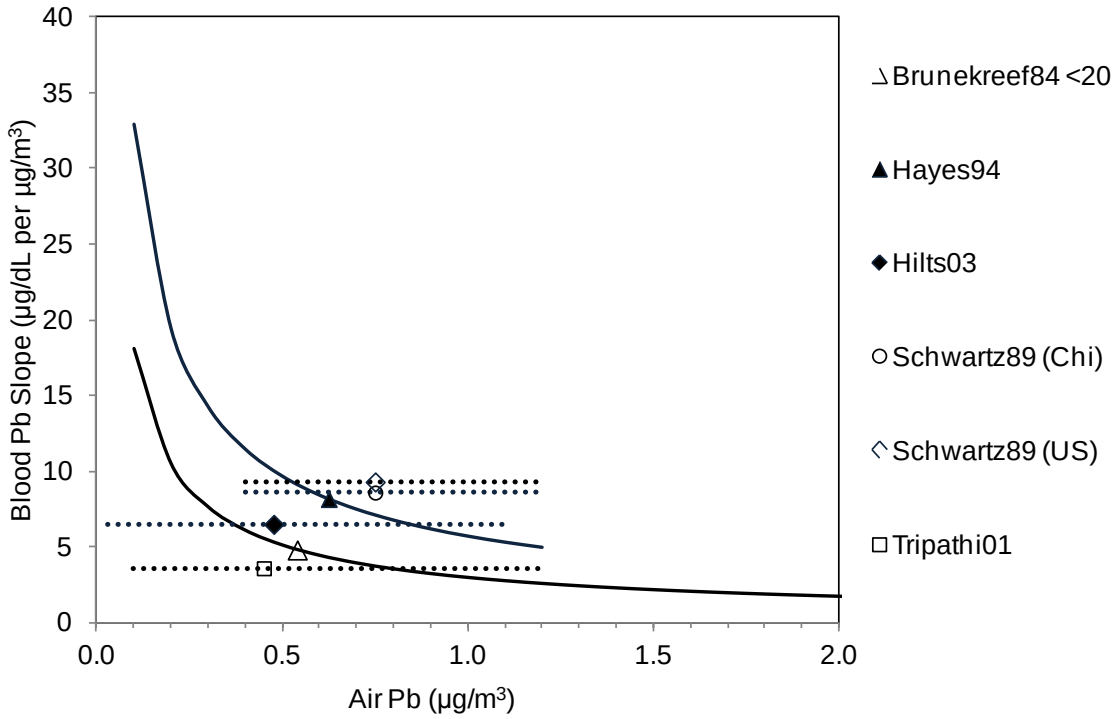
GM, geometric mean; GSD, geometric standard deviation; PbB, blood Pb concentration (µg/dL); PbA, air Pb concentration (µg/m^3)



Note: The regression model is: (ln[µg/dL blood Pb] = 0.3485·ln[µg/m^3 air Pb] + 2.85) for all children (n=96 subject groups) and (ln[µg/dL blood Pb] = 0.2159·ln[µg/m^3 air Pb] + 2.62) when the sample was restricted to populations that had blood Pb concentrations <20 µg/dL (n=44 subject groups).

Data provided from Brunekreef (1984).

Figure 4-22 Predicted relationship between air Pb and blood Pb based on a meta analysis of 18 studies.



Note: Slopes are calculated for a change in air Pb (±0.01 µg/m^3) over ranges of air Pb concentrations reported in each study (lines). The air Pb axis is truncated at 2 µg/m^3; the actual range for the Brunkreef et al. (1984) study was 0.1-6.4 µg/dL per µg/m^3. The slope axis has been truncated at 40; the actual range for the Hayes et al. (1994) study was 5-56 µg/dL per µg/m^3 (the high end of the range was estimated for the minimum annual average air Pb of 0.05 µg/m^3). The two estimates for Schwartz and Pitcher (1989) represent data for U.S. and Chicago. Models are log-log (solid lines) and linear (dotted lines). Symbols show the slope at the central estimate of air Pb (e.g., median for Brunereef and mean for the other studies).

Figure 4-23 Blood Pb – air Pb slopes (µg/dL per µg/m^3) predicted from epidemiologic studies.

Hilts et al. (2003) reported child blood Pb and air Pb trends for the city of Trail, British Columbia, over a period preceding and following installation of a new smelter process in 1997 which resulted in lower air Pb concentrations. Blood Pb data were obtained from annual (1989-2001) surveys of children 6-60 months of age who lived within 4 km from the smelter (n: 292-536 eligible per year, 75-85% participation). Air Pb concentrations were obtained from high volume suspended particulate samplers placed within 2 km of the smelter that operated 24 hours every 6th day. Data on Pb levels in air, residential soil, interior dust, and blood for three sampling periods are summarized in Table 4-13. Based on these data, blood Pb decreased 6.5 µg/dL per 1 µg/m^3 air Pb and by 0.068 µg/dL per mg/kg soil Pb (based on linear regression with air or soil Pb as the sole independent variable) for the entire period. When considering a 9-month weighted mean of 0.13 µg/m^3) for 2001 (3 months when the smelter was closed, 0.03 µg/m^3; 6 months when it was open, 0.18 µg/m^3), the slope is 7.0. Several uncertainties apply to these

estimates. Potential mismatching of air Pb concentrations (often termed misclassification) with individual blood Pb levels may have occurred as a result of air Pb being measured within 2 km of the smelter, whereas, the blood Pb data included children who resided >2 km from the smelter. The regression estimates were based on group mean estimates for three sampling dates, rather than on the individual blood Pb estimates, which included repeated measures on an unreported fraction of the sample. The limited number of data pairs (three) constrained parameter estimates to simple regression coefficients. Other important factors probably contributed to blood Pb declines in this population that may have been correlated with air, soil and dust Pb levels. These factors include aggressive public education and exposure intervention programs (Hilts et al., 1998; Hilts, 1996). Therefore, the coefficients shown in Table 4-13 are likely to overestimate the influence of air, dust, or soil Pb on blood Pb concentrations at this site.

Table 4-13 Environmental Pb levels and blood Pb levels in children in Trail, British Columbia.

Date	1996 [a]	1999	2001	Regression Coefficient
Blood Pb (µg/dL)	11.5	5.9	4.7	NA
Air Pb (µg/m^3)	1.1	0.3	0.13 [b]	7.01 ± 0.009 (R^2=1.00, p=0.001)
Soil Pb (mg/kg)	844	756	750 [c]	0.069 ± 0.008 (R^2=0.99, p=0.069)
Interior Dust Pb (mg/kg)	758	583	580 [c]	0.035 ± 0.005 (R^2=0.98, p=0.097)

A new smelter process began operation in 1997. Values for air, soil and dust Pb are annual geometric means; values for blood Pb are annual geometric means. Regression coefficients are for simple linear regression of each exposure variable on blood Pb.

[a] Values for air Pb, soil Pb, and interior dust Pb are actually for period of 1994-1996.

[b] Nine month time-weighted average of 0.03 µg Pb/m^3 for 3 months and 0.18 µg Pb/m^3 for 6 months.

[c] Values assumed by study authors.

Source: Data from Hilts et al. (2003).

Ranft et al. (2008) reported a meta-analysis of five cross-sectional surveys of air and soil Pb levels and blood Pb concentrations in children living in Duisburg, Germany. The analysis included observations on 843 children (6-11 years of age) made during the period 1983-2000. Children recruited in 1983 were an average of 9.1 yrs of age, whereas children recruited in later years of the study averaged 6.3 to 6.4 yrs of age. The 1983 air Pb concentrations were based on two monitoring stations, while a combination of dispersion modeling and monitoring data was used in the later years to estimate Pb in PM in a 200 meter by 200 meter grid that encompassed the city. Pb in surface soil (0-10 cm) was measured at 145 locations in the city in 2000 and 2001. Air and soil Pb concentrations were assigned to each participant by spatial interpolation from the sampling grid data to each home residence. The 5th-95th percentile ranges were 0.025-0.465 µg Pb/m^3 for air and 72-877 mg Pb/kg for soil. The results of multivariate

regression analyses were reported in terms of the relative increase (the geometric mean blood Pb ratio, GMR) for an increase in air or soil Pb from the 5th to 95th percentile value. In a multivariate regression model (equation not provided) that included air and soil Pb in the same model and adjusted for covariates, the GMR values were: 2.55 per 0.44 µg/m^3 increase in air Pb (95% CI: 2.40, 2.71, R^2=0.484, p <0.001) and 1.30 per 800 mg/kg soil Pb (95% CI: 1.19, 1.43, R^2 = 0.017, p <0.001). Based on the values for R^2, the regression model accounted for approximately 59% of the total variance in blood Pb and, of this, 83% was attributed to air Pb. Values for GMR for soil Pb ranged from 1.41 to 2.89, with most recent blood Pb data (from the year 2000) yielding a value of 1.63 per 800 mg/kg increase in soil Pb. The GMR values can be converted to regression slopes (slope = [starting blood Pb×ln(GMR)]/[95th − 5th percentile air or soil Pb]) for calculating equivalent air:blood Pb ratios. The model predicts an increase of 3.2 µg/dL blood Pb per 1 µg/m^3 increase in air Pb at the median air Pb concentration for the study (0.1 µg/m^3) and assuming a background blood Pb concentration of 1.5 µg/dL. Based on the GMR estimate of 1.63 for soil Pb, a 1,000 mg/kg increase in soil Pb would be associated with an increase in blood Pb of 0.9 µg/dL per mg/kg soil at the median soil Pb concentration of 206 mg/kg and assuming a background blood Pb concentration of 1.5 µg/dL. The degree of confounding of the GMR and estimates resulting from the air and soil Pb correlation was not reported, although the correlation coefficient for the two variables was 0.136 for the whole data set and 0.703 when data collected in 1983 was omitted. Because the model also included Pb levels in soil, the blood Pb-air Pb ratio may be underestimated since some of the Pb in soil was likely derived from air. The blood Pb-air Pb slope does not include the portion of the soil/dust Pb ingestion pathway that derives from air Pb, such as recently airborne Pb deposited to soil and dust which remains available for inhalation and ingestion.

To estimate the blood Pb-air Pb ratio that included all air-related pathways, data for median of blood Pb and air Pb among the cohort of children studied were extracted from Table 2 in Ranft et al. (2008) for each of the five study years. The median blood Pb and air Pb were used in regressions employing linear, log-log, and log-linear (i.e., similar to authors' approach with ln[blood Pb] against air Pb) fits. The linear model obtained was: PbB = 12.2×PbA + 3.0 (R^2 = 0.96); i.e., the linear regression produced a constant slope of 12 µg/dL per µg/m^3. The log-log model was: ln(PbB) = 0.36×ln(PbA) + 2.4 (R^2 = 0.90), resulting in an inverse curve for dPbB/dPbA, versus PbA with a slope of 17 µg/dL per µg/m^3 at PbA = 0.1 µg/m^3. The log-linear model was: ln(PbB) = 2.2×PbA + 1.2 (R^2 = 0.90), resulting in an exponential curve of dPbB/dPbA, versus PbA, with a slope of 8.7 µg/dL per µg/m^3 at PbA = 0.1 µg/m^3. Geometric mean data for blood Pb and air Pb are also available from Figure 1 in Ranft et al. (2008) and provide similar regression coefficients and R^2 values to those described above using median values.

Schnaas et al. (2004) analyzed data on blood Pb and air Pb concentrations during and after the phase out of leaded gasoline use in Mexico (1986-1997) in children as part of a prospective study conducted in Mexico City. The sample included 321 children born during the period 1987 through 1992. Repeated blood Pb measurements were made on each child at 6-month intervals up to age 10 years. Air Pb measurements (annual average of quarterly means) were derived from three area monitors which represented distinct study zones. Children were assigned to study zones based on their current address. Associations between lifetime (across the first 10 years of life) blood Pb concentration, air Pb concentration (mean annual for each calendar year of study) and other variables (e.g., age, year of birth, family use of glazed pottery) were evaluated using multivariate regression models. The largest air Pb coefficient occurred in the cohort born in 1987, who experienced the largest decline in air Pb (from 2.8 to about 0.25 μg/m^3); the air Pb coefficient for this group of children was 0.213 (95% CI: 0.114-0.312) ln [μg/dL blood] per ln[μg/m^3 air]. The smallest, statistically significant air Pb coefficient occurred for the 1990 birth year cohort, who experienced a decline in air Pb from 1.5 to about 0.1 μg/m^3. The air Pb coefficient for the 1990 cohort was 0.116 (95% CI: 0.035-0.196). Based on these air Pb coefficients, children in the 1987 and 1990 cohorts were estimated to have 24% and 12% decreases in lifetime (across the first 10 years of life) blood Pb levels, respectively, per natural log decrease in air Pb. Table 4-14 provides predicted blood Pb and blood Pb-air Pb slopes as a function of age for the 1987 and 1990 cohorts. The values in Table 4-14 are for children having complete datasets that lived in the Merced (study region having medium air Pb concentrations) of Mexico City in medium SES families (for the study population) that did not use clay pottery. Higher estimated blood Pb and blood Pb-air Pb slopes than those in Table 4-14, would be predicted for low SES families living in Xalostoc (study region having highest air Pb) that use clay pottery (e.g., 2-yr-olds predicted blood Pb of 11–14 μg/dL and blood Pb-air Pb slope of 5.7–7.2 μg/dL per μg/m^3). Conversely, lower estimates would be predicted for high SES families living in Pedregal (study region having lowest air Pb) that did not use clay pottery (e.g., 2-yr-olds predicted blood Pb of 7–9 μg/dL and blood Pb-air Pb slope of 3.8–4.8 μg/dL per μg/m^3). The effect of air Pb on blood Pb may have been underestimated in this study due to inclusion of location and SES terms in the regression model. It was specifically noted by the authors that air Pb differed significantly between the locations and the poorer residential areas were usually the more industrialized areas with higher pollution. Hence, the inclusion of these terms may have accounted for some of the variance in blood Pb attributable to air Pb.

Table 4-14 Predicted blood Pb levels and blood-air slopes for Mexico City children (1987 and 1990 cohorts).

Age (in years)	Blood Pb (µg/dL)	Blood Pb–Air Pb Slope (µg/dL per µg/m^3)
1	7.4 – 8.5 [a]	2.1 – 4.5 [a]
2	8.9 – 10.2	2.6 – 5.5
3	8.4 – 9.7	2.4 – 5.2
4	7.9 – 9.1	2.3 – 4.9
5	7.7 – 8.8	2.2 – 4.7
6	6.9 – 7.9	2.0 – 4.2
7	6.8 – 7.8	2.0 – 4.2
8	6.1 – 7.1	1.8 – 3.8
9	5.8 – 6.7	1.7 – 3.6
10	5.6 – 6.5	1.6 – 3.5

[a]Values are for 1990 and 1987 cohorts, respectively, at an air Pb concentration of 0.4 µg/m^3 which is the median and geometric mean of the annual air Pb concentrations over the course of the study based on data in Figure 1 of Schnaas et al. (2004)

Source: Based on Table 4 of Schnaas et al. (2004)

For an approach that considers all the Schnaas et al. (2004) cohorts simultaneously, data for annual geometric mean of blood Pb and air Pb were extracted from Figure 1 in Schnaas et al. (2004). However, in employing this approach, blood Pb is confounded by age and year because in the early years of the study, only younger children were available and in the later years of the study, only older children contributed data. The extracted values of the geometric mean of blood Pb and mean air Pb were used in regressions employing linear and log-log models for comparison to other studies. The linear model obtained was: PbB = 2.50×PbA + 5.61 (R^2 = 0.84), i.e., the linear model produced a constant slope of 2.50 µg/dL per µg/m^3. However, inspection of the graph (not shown here) suggested a bi-linear fit. Regression of the data over the interval 0.1-0.4 µg/m^3 produced a slope of 9.0 µg/dL per µg/m^3 (R^2 = 0.83), and regression of the data over the interval 0.4-2.8 µg/m^3 produced a slope of 1.52 µg/dL per µg/m^3 (R^2 = 0.83). The log-log model was: ln(PbB) = 0.26×ln(PbA) + 2.20 (R^2 = 0.94), resulting in an inverse curve for dPbB/dPb, versus PbA, with a slope of 4.5 µg/dL per µg/m^3 at PbA = 0.4 µg/m^3.

Schwartz and Pitcher (1989) reported a multivariate regression analysis of associations between U.S. gasoline Pb consumption (i.e., sales) and blood Pb concentrations in the U.S. population during the period 1976-1980 when use of Pb in gasoline was being phased out. Although this analysis did not directly derive a slope for the air Pb-blood Pb relationships, other analyses have shown a strong correlation between U.S. gasoline Pb consumption and ambient air Pb levels during this same period (U.S. EPA, 1986a). Therefore, it is possible to infer an air Pb-blood Pb relationship from these data. Two

sources of blood Pb data were used in Schwartz and Pitcher (1989): NHANES II provided measurements for U.S. individuals 6 months to 74 years of age (n = 9,987 subjects) between February 1976 and February 1980, and the Chicago blood Pb screening program provided measurements in black children aged birth to 5 years (n = 5476 subjects) for the period from 1976 to mid-1980. Observed blood Pb levels were not provided. Gasoline Pb consumption for the U.S. was estimated as the product of monthly gasoline sales and quarterly estimates of Pb concentrations in gasoline reported to U.S. EPA. Based on the NHANES blood Pb data for whites, the regression coefficient for blood Pb on the previous month's gasoline Pb usage, adjusted for age, race, sex, income, degree of urbanization, nutrient intake, smoking, alcohol consumption, occupational exposure, and other significant covariates was 2.14 µg/dL blood per 100 metric tons of gasoline Pb/day (SE=0.19, p=0.0000); the authors reported that the results for blacks were essentially identical. Based on the Chicago blood Pb data, the age-adjusted regression coefficient was 16.12 (µg/dL per 1,000 metric tons gasoline Pb/quarter [SE=1.37, p=0.0001]). When the coefficient was scaled by the ratio of Chicago's gasoline use to the nation's and converted to units of 100 metric tons per day, the gasoline Pb coefficient was 1.97 µg/dL blood per 100 metric tons of gasoline Pb/day), which is similar to the coefficient reported for the NHANES cohort. U.S. EPA (1986a) reported data on gasoline Pb consumption (sales) and ambient Pb levels in the U.S. during the period 1976-1984 (Table 4-15). Based on these data, air Pb concentrations decreased in association with gasoline Pb consumption. The linear regression coefficient for the air Pb decrease was 0.23 µg/m^3 per 100 metric tons gasoline Pb/day (SE = 0.02, $R^{2 =}$ 0.95, p <0.0001). If this regression coefficient is used to convert the blood Pb slopes from Schwartz and Pitcher (1989), the corresponding air Pb-blood Pb slopes would be 9.3 and 8.6 µg/dL per µg/m^3, based on the NHANES and Chicago data, respectively (e.g., 2.14/0.23 = 9.3 and 1.97/0.23=8.6).

Table 4-15 U.S. gasoline Pb consumption and air Pb levels.

Date	Total Gasoline Pb (10^3 metric tons/year)	Total Gasoline Pb (10^2 metric tons/day)[a]	Air Pb (µg/m^3) [b]
1976	171.4	4.70	1.22
1977	168.9	4.63	1.20
1978	153.0	4.19	1.13
1979	129.4	3.53	0.74
1980	78.8	2.16	0.66
1981	60.7	1.66	0.51
1982	59.9	1.64	0.53
1983	52.3	1.43	0.40
1984	46.0	1.26	0.36

The linear regression coefficient is 0.23 µg/m^3 air per 100 metric tons/day (SE= 0.020, R^2 = 0.95, p <0.0001)

[a]Conversion factor is 10/365 days/year.

Tripathi et al. (2001) reported child blood Pb and air Pb for the city and suburbs of Mumbai, India over the period 1984-1996. Pb-free petroleum was introduced in India beginning in late 1996, which was outside the period of this study. Blood Pb data were obtained from children 6-10 years of age (n = 544) who lived in 13 locations within the Mumbai area. Air Pb concentrations were measured from high volume PM samplers (with the majority of Pb in the respirable size range) placed at a height of 1.6 meters that operated 24 hours. Data on Pb concentrations in air and blood are summarized in Table 4-16. An additional 16 children from two regions of Mumbai were excluded from the analysis because of their high blood Pb levels (geometric means: 69.2 and 20.8 µg/dL) and proximity to industrial Pb sources with high air Pb concentrations (geometric means: 41.2 and 6.7 µg/m^3). Based on the data from residential locations presented in Table 4-16, blood Pb increased 3.6 µg/dL per 1 µg/m^3 air Pb (based on linear regression with air Pb as the sole independent variable). Several uncertainties apply to these estimates, including potential exposure misclassification since the mean air Pb concentration was used for each suburb over the entire study period. In addition, the regression estimates were based on group mean blood Pb estimates for the 13 sampling locations, rather than on the individual blood Pb estimates. Ingestion of Pb-containing food was estimated in this study, but was not considered in the regression equation for estimating blood Pb, despite the author's conclusion that the ingestion route is important for the intake of Pb by children in Mumbai.

Table 4-16 Air Pb concentrations and blood Pb levels in children in Mumbai, India.

	Blood Pb (µg/dL)			Air Pb (µg/m^3)		
Location	**N**	**GM**	**GSD**	**N**	**GM**	**GSD**
Borivilli	12	10.4	1.67	10	0.32	1.51
Byculla	117	11.0	1.99	30	0.99	1.73
Deonar	46	9.5	2.29	93	0.11	3.21
Goregaon	21	9.1	1.30	24	0.35	1.77
Govandi	20	8.9	1.42	10	0.10	1.52
Jogeshwari	20	8.6	1.32	24	0.11	2.47
Khar	17	9.0	1.53	22	0.18	3.15
Parel	168	10.4	1.91	37	0.44	1.48
Sion	34	9.6	1.49	96	0.39	1.75
Thans (SS)	37	12.0	1.86	4	1.18	1.04

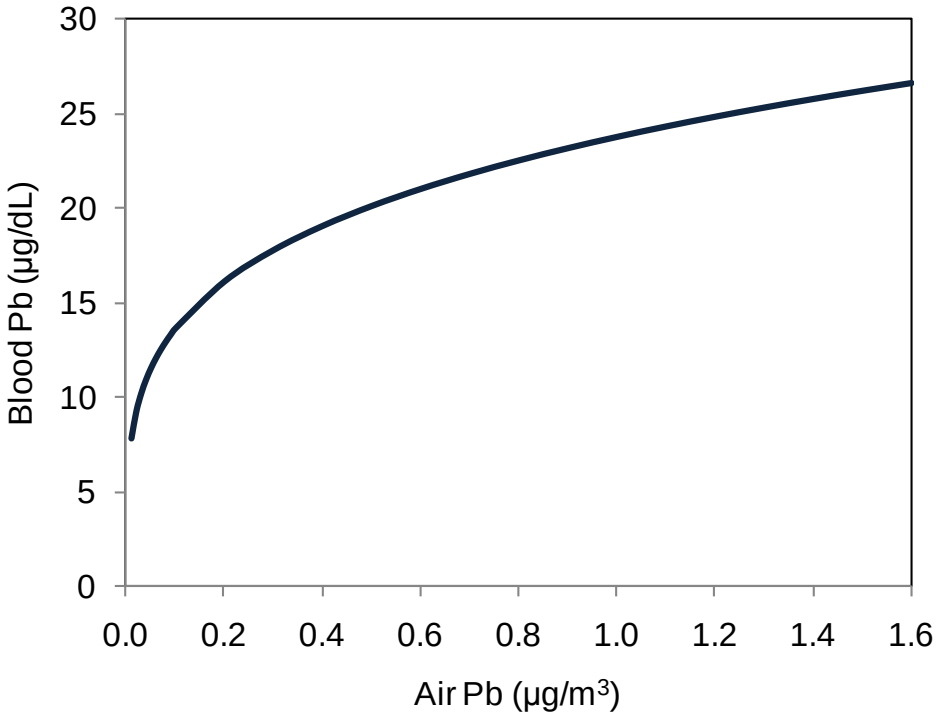
The linear regression coefficient is 3.62 µg/dL blood per µg/m^3 air (SE= 0.61, R^2= 0.76, p <0.001).
GM, geometric mean; GSD, geometric standard deviation; N, number of subjects.

Source: Data are from Tripathi et al. (2001).

Hayes et al. (1994) analyzed data collected as part of the Chicago, IL blood Pb screening program for the period 1974-1988, following the phase-out of leaded gasoline. The data included 9,604 blood Pb measurements in children (age: 6 months to 5 years) and quarterly average air Pb concentrations measured at 12 monitoring stations in Cook County, IL. Annual median blood Pb levels declined from 30 µg/dL in 1968 to 12 µg/dL in 1988. During most of the years of the study, blood Pb measurements at or below 10 µg/dL were recorded as 10 µg/dL because of concerns over measurement accuracy of the instrument below these levels. Quarterly median blood Pb levels declined in association with quarterly mean air Pb concentrations. The regression model predicted a slope of 0.24 ln [µg/dL blood] per ln[µg/m^3 air], as illustrated in Figure 4-24. This slope corresponds to an increase of 8.2 µg/dL blood Pb per µg/m^3 at the average annual mean air Pb concentration of 0.62 µg/m^3. As shown in Figure 4-25, with decreasing air Pb concentration, the slope increases. The study reports a slope of 5.6 associated with ambient air Pb levels near 1 µg/m^3 and a slope of 16 for ambient air Pb levels in the range of 0.25 µg/m^3, indicating a pattern of higher ratios with lower ambient air Pb and blood Pb levels.



Note: The regression model is: (ln[µg/dL blood Pb] = 0.24·ln[µg/m^3 air Pb] + 3.17).
Modified from Hayes et al. (1994).

Figure 4-24 Predicted relationship between air Pb and blood Pb based on data from Chicago, IL in children age 0-5 years (1974–1988).

The evidence on the quantitative relationship between air Pb and blood Pb is now, as in the past, limited by the circumstances in which the data are collected. These estimates are generally developed from studies of populations in various Pb exposure circumstances. The 1986 Pb AQCD (U.S. EPA, 1986a) discussed the studies available at that time that addressed the relationship between air Pb and blood Pb, recognizing that there is significant variability in air-to-blood ratios for different populations exposed to Pb through different air-related exposure pathways and at different exposure levels. The 1986 Pb AQCD noted that ratios derived from studies involving higher blood and air Pb levels are generally smaller than ratios from studies involving lower blood and air Pb levels [see the 1986 Pb AQCD, Chapter 11, pp 99 (U.S. EPA, 1986a)]. In consideration of this factor, slopes in the range of 3 to 5 for children generally reflected study populations with blood Pb levels in the range of approximately 10–30 µg/dL [see Chapter 11, pp 100 of the 1986 Pb AQCD, Table 11-36, from (Brunekreef, 1984)], much higher than those common in today's population. The slope of 3.6 from Tripathi et al. (2001) is consistent with this observation, given that the blood Pb levels were at the lower end of this range (i.e., 10-15 µg/dL).

There are fewer studies that evaluate the air Pb-blood Pb relationship in conditions that are more reflective of the current state. Hilts et al. (2003) is one such study that provides insight because the blood Pb and air Pb levels were relatively lower than those studies mentioned above; the slope reported was 6.5, but could be as high as 7.0. Similarly, Hayes et al. (1994) demonstrates greater slopes observed with decreasing air Pb concentrations. These studies provide evidence that air-to-blood slopes relevant for today's population of children would likely extend higher than the 3 to 5 range identified in the 1986 Pb AQCD (U.S. EPA, 1986a). In the 2008 final rule for the Pb NAAQS (73 FR 66964), with recognition of uncertainty and variability in the absolute value of an air-to-blood relationship, the air-to-blood slopes of 5, 7, and 10 µg/dL per µg/m^3 were utilized in evaluating air-related IQ loss of children. Figure 4-25 illustrates the impact of these air-to-blood slopes on the estimated change in air-related blood Pb as a function of change in air Pb.

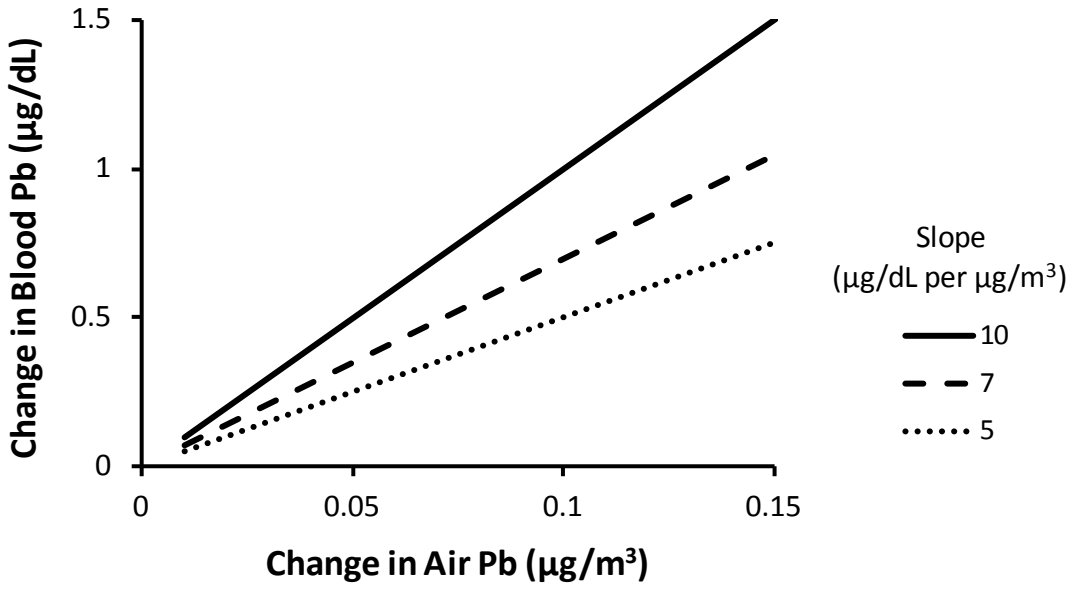


Figure 4-25 Effect of air-to-blood slope on estimated change in air-related blood Pb with change in air Pb.

4.5.2 Air Pb-Blood Pb Relationships in Occupational Cohorts

At the time of the 1986 Pb AQCD, there was a great deal of information on blood Pb responses to air Pb exposures of workers in Pb-related occupations (U.S. EPA, 1986a). Almost all such exposures were at air Pb exposures far in excess of typical non-occupational exposures and typically did not account for other potential sources of Pb exposure. The air Pb-blood Pb slopes in these studies were generally much less (i.e., 0.03-0.2; pg 11-106) than those observed in children when considering aggregate air Pb contributions (i.e., 3-5; pg 11-106). In addition, the air Pb concentrations in occupational studies are typically collected at much shorter durations (e.g., over an 8-hr workday) compared to ambient Pb monitoring, making it difficult to draw comparisons between occupationally and non-occupationally exposed populations. Therefore, only a few occupational studies are presented below to demonstrate that more recent air Pb and blood Pb levels remain much higher in these studies compared to those conducted in the general population.

Rodrigues et al. (2010) examined factors contributing to variability in blood Pb concentration in New England bridge painters, who regularly use electric grinders to prepare surfaces for painting. The study included 84 adults (83 males, 1 female) who were observed during a 2-week period in 1994 or 1995. The geometric mean air Pb concentration obtained from personal PM samplers worn over the workday was 58 µg/m^3 (GSD 2.8), with a maximum daily value of 210 µg/m^3. Hand wipe samples were collected and analyzed for Pb (GM = 793 µg, GSD 3.7). Blood Pb samples were collected at the beginning of the 2-week period (GM = 16.1 µg/dL, GSD 1.7) and at the end of the period (GM=18.2 µg/dL, GD=1.6). Associations between exposure variables and blood Pb concentrations were explored with multivariate regression models. When the model excluded hand-wipe data, the regression coefficient for the relationship between ln[blood Pb concentration (µg/dL)] and ln[air Pb (µg/m^3)] was 0.11 (SE = 0.05, p = 0.03). This corresponds to a slope of 0.009 µg/dL per µg/m^3 at the geometric mean air Pb concentration for the study. A second regression model included hand wipe Pb (n = 54) and yielded a regression coefficient of 0.05 (SE = 0.07, p = 0.45), which corresponds to a slope of 0.02 µg/dL per µg/m^3 at the geometric mean air Pb concentration for the study.

Two other studies that examined the air Pb-blood Pb relationship in occupational settings at higher air Pb concentrations (geometric mean of 82 and 111 µg/m^3) for Pb battery and crystal workers, respectively (Pierre et al., 2002; Lai et al., 1997). Blood Pb levels for the Pb battery workers averaged 56.9 µg/dL (SD 25.3) and for the crystal workers was 21.9 µg/dL. Both studies employed log-log regression models, resulting in slopes of 0.49 (Pierre et al., 2002) and 0.08 (Lai et al., 1997).

4.5.3 Environmental Pb-Blood Pb Relationships

Empirically-based relationships between blood Pb levels and Pb intakes and/or Pb concentrations in environmental media have provided the basis for what has become known as slope factor models. Slope factor models are highly simplified representations of empirically based regression models in which the slope parameter represents the change in blood Pb concentration projected to occur in association with a change in Pb intake or uptake. The slope parameter is factored by exposure parameters (e.g., exposure concentrations, environmental media intake rates) that relate exposure to blood Pb concentration (Maddaloni et al., 2005; U.S. EPA, 2003c; Abadin and Wheeler, 1997; Stern, 1996; Bowers et al., 1994; Stern, 1994; Carlisle and Wade, 1992). In slope factor models, Pb biokinetics are represented as a linear function between the blood Pb concentration and either Pb uptake (uptake slope factor, USF) or Pb intake (intake slope factor, ISF). The models take the general mathematical forms:

$$\mathbf{PbB = E \times ISF}$$

Equation 4-2

$$\mathbf{PbB = E \times AF \times USF}$$

Equation 4-3

where PbB is the blood Pb concentration, E is an expression for exposure (e.g., soil intake × soil Pb concentration) and AF is the absorption fraction for Pb in the specific exposure medium of interest. Intake slope factors are based on ingested rather than absorbed Pb and, therefore, integrate both absorption and biokinetics into a single slope factor, whereas models that utilize an uptake slope factor include a separate absorption parameter. In contrast to mechanistic models, slope factor models predict quasi-steady state blood Pb concentrations that correspond to time-averaged daily Pb intakes (or uptakes) that occur over sufficiently long periods to produce a quasi-steady state (i.e., >75 days, ~3 times the $t_{1/2}$ for elimination of Pb in blood).

The U.S. EPA *Adult Lead Methodology* (ALM) is an example of a slope factor model that has had extensive regulatory use in the EPA Superfund program for assessing health risks to adults associated with non-residential exposures to Pb in contaminated soils (Maddaloni et al., 2005; U.S. EPA, 1996a). The model was developed to predict maternal and fetal blood Pb concentrations that might occur in relation to maternal exposures to contaminated soils. The model assumes an uptake slope factor of 0.4 µg/dL blood per µg/day Pb uptake. Additional discussion of slope factor models that have been used or proposed for regulatory use can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

Previous studies included in the 2006 Pb AQCD (U.S. EPA, 2006b) explored the relationship between blood Pb in children and environmental Pb concentrations. In a pooled analysis of 12 epidemiologic studies, interior dust Pb loading, exterior soil/dust Pb, age, mouthing behavior, and race were all statistically significant variables included in the regression model for blood Pb concentration (Lanphear et al., 1998). Significant interactions were found for age and dust Pb loading, mouthing behavior and exterior soil/dust level, and SES and water Pb level. In a meta-analysis of 11 epidemiologic studies, among children the most common exposure pathway influencing blood Pb concentration in structural equation modeling was exterior soil, operating through its effect on interior dust Pb and hand Pb (Succop et al., 1998). Similar to Lanphear et al. (1998), in the linear regression model, interior dust Pb loading had the strongest relationships with blood Pb concentration. Individual studies conducted in Rochester, NY, Cincinnati, OH, and Baltimore, MD report similar relationships between children's blood Pb and interior dust concentrations (Lanphear and Roghmann, 1997; U.S. EPA, 1996b; Bornschein et al., 1985).

Dixon et al. (2009) reported a multivariate analysis of associations between environmental Pb concentrations and blood Pb concentrations, based on data collected in the NHANES (1999-2004). The analyses included 2,155 children, age 12-60 months. The population-weighted geometric mean blood Pb concentration was 2.03 µg/dL (GSD 1.03). A linear model applied to these data yielded an R^2 of 40% (Table 4-17). The regression coefficient for the relationship between ln[blood Pb concentration (µg/dL)] and ln[floor dust Pb concentration (µg/ft^2)] was 0.386 (SE 0.089) for "not smooth and cleanable" surfaces (e.g., high-pile carpets) and 0.205 (SE 0.032) for "smooth and cleanable" surfaces (e.g., uncarpeted or low-pile carpets). These coefficients correspond to a 2.4-fold or 1.6-fold increase in blood Pb concentration, respectively, for a 10-fold increase in floor dust Pb concentration.

Table 4-17 Linear model relating environmental Pb exposure and blood Pb concentration in children.

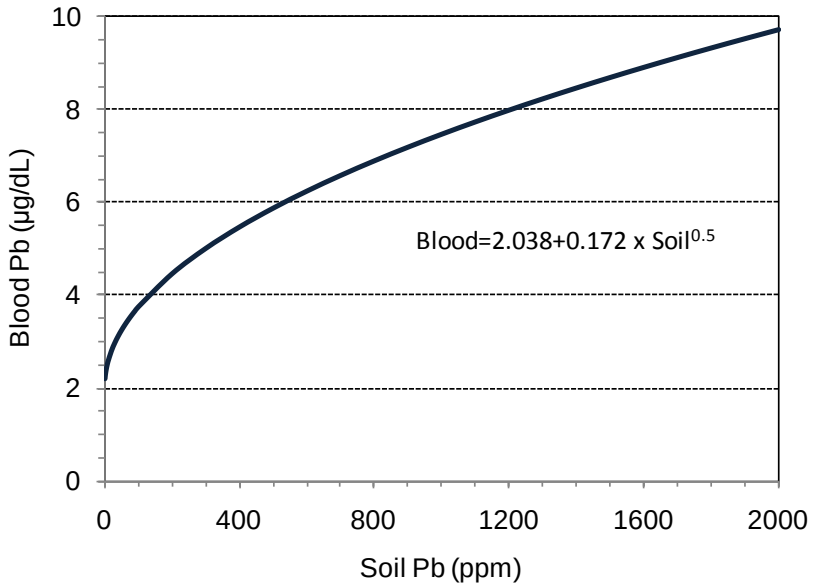
Source: Dixon et al. (2009).

Mielke et al. (2007a) analyzed blood Pb and soil Pb concentration data collected as part of a blood Pb screening program in New Orleans, Louisiana (2000-2005). The data set included 55,551 blood Pb measurements for children 0-6 years of age and 5,467 soil Pb measurements. Blood Pb and soil Pb concentrations were matched at the level of census tracts. The association between blood Pb concentration and soil Pb concentration was evaluated using non-parametric permutation methods. The resulting best-fit model was:

$$\mathbf{PbB} = \mathbf{2.038} + (\mathbf{0.172} \times \mathbf{PbS}^{\mathbf{0.5}})$$

Equation 4-4

where PbB is the median blood Pb concentration and PbS is the median soil Pb concentration. Although the overall association between blood Pb and soil Pb was strong (R^2=0.528), there was considerable scatter in the data. For example, at the median soil Pb levels of 100 and 500 mg/kg, median blood Pb ranged from 2 to 8 µg/dL and 3 to 12 µg/dL, respectively. The resulting curvilinear relationship predicts a twofold increase in blood Pb concentration for an increase in soil Pb concentration from 100 to 1,000 ppm (Figure 4-26).



Note: The data set included 55,551 blood Pb measurements for children 0-6 years of age and 5,467 soil Pb measurements. Blood Pb and soil Pb concentrations were matched at the level of census tracts (Mielke et al., 2007a).

Figure 4-26 Predicted relationship between soil Pb concentration and blood Pb concentration in children based on data collected in New Orleans, Louisiana: 2000-2005.

In a subsequent re-analysis of the New Orleans (2000-2005) data, individual child blood Pb observations were matched to census tract soil concentrations (Zahran et al., 2011). This analysis confirmed the association between blood Pb and both soil Pb and age reported in Mielke et al. (2007a). Regression coefficients for soil Pb (random effects generalized least squares regression) ranged from 0.217 to 0.214 (per soil $Pb^{0.5}$), which is equivalent to approximately a 2-fold increase in blood Pb concentration for an increase in soil Pb concentration from 100 to 1,000 ppm.

Several studies have linked elevated blood Pb levels to residential soil exposures for populations living nearby industrial or mining facilities. Gulson et al. (2009) studied the blood Pb and isotopic Pb ratios of children younger than 5-years old and adults older than 18-years old living in the vicinity of a mine producing Magellan Pb ore in western Australia. They observed a median blood Pb level of 6.6 µg/dL for the children, with isotopic ratios indicating contributions from the mine ranging from 27 to 93%. A weak but significant linear association between blood Pb level and percent Magellan Pb was observed ($R^2 = 0.12$, $p = 0.018$). Among children with blood Pb levels over 9 µg/dL and among adults, the isotopic ratios revealed Pb exposures from a variety of sources. Garavan et al. (2008) measured soil Pb and blood Pb levels among children aged 1-month to 17.7-years old in an Irish town near a coal mine. The blood Pb measurements were

instituted as part of a screening and community education program given that the presence of Pb had been documented in the environment. Garavan et al. (2008) found that over 3 years of the screening period, median blood Pb levels reduced by roughly 22% from 2.7 to 2.1 µg/dL.

An extensive discussion of the relationships between environmental Pb levels and blood Pb concentrations in children at the Bunker Hill Superfund Site location, a former Pb mining and smelting site, was provided in the 2006 Pb AQCD (U.S. EPA, 2006c). In the most recent analysis (TerraGraphics Environmental Engineering, 2004) of the data on environmental Pb levels and child blood Pb concentrations (1988-2002), blood Pb concentrations (annual GM) ranged from 2.6 to 9.9 µg/dL. Environmental Pb levels (e.g., dust, soil, paint Pb levels) data were collected at ~3,000 residences, with interior dust Pb concentrations (annual GM) ranging from ~400 to 4,200 mg/kg and yard soil Pb concentration (annual GM) ranging from ~150 to 2,300 mg/kg. Several multivariate regression models relating environmental Pb levels and blood Pb concentration were explored; the model having the highest R^2 (0.26) is shown in Table 4-18. The model predicts significant associations between blood Pb concentration, age, interior dust, yard soil, neighborhood soil (geometric mean soil Pb concentration for areas within 200 ft of the residence), and community soil Pb concentration (community GM). Based on the standardized regression coefficients, the community soil Pb concentration had the largest effect on blood Pb concentration, followed by neighborhood soil Pb concentration, interior dust Pb concentration, and yard soil Pb concentration (Table 4-18). The model predicted a 1.8 µg/dL decrease in blood Pb concentration in association with a decrease in community soil Pb concentration from 2,000 to 1,000 mg/kg. The same decrease in neighborhood soil Pb concentration, interior dust Pb concentration, or yard soil Pb concentration was predicted to result in a 0.8, 0.5, or 0.2 µg/dL decrease in blood Pb concentration, respectively. Note that the soil Pb component of the model was similar to that derived by Lewin et al. (1999), in which a model of blood Pb as a function of soil Pb among 0-6 year old children living near one of four industrial sites was given as PbB = 0.2438ln(PbS} + 0.2758.

Table 4-18 General linear model relating blood Pb concentration in children and environmental Pb levels—Bunker Hill Superfund Site.

Parameter	Coefficient	P-value	Standardized Coefficient
Intercept	-0.1801	0.7916	0.00000
Age (yr)	-0.4075	<0.0001	-0.2497
ln(interior dust Pb); (mg/kg)	0.7288	<0.0001	0.1515
ln(yard soil Pb); (mg/kg)	0.2555	0.0002	0.0777
GM soil Pb within 200 ft of residence (mg/kg)	0.0008	<0.0001	0.1380
GM community soil Pb (mg/kg)	0.0018	<0.0001	0.2250

R^2 = 0.264; p <0.0001; based on data from Bunker Hill Superfund Site, collected over the period 1988-2002.
GM: geometric mean; ln: natural log.

Malcoe et al. (2002) analyzed 1997 data on blood Pb and environmental Pb concentrations in a representative sample of Native American and white children (n = 224, age 1-6 years) who resided in a former Pb mining region in Ottawa County, OK. The data set included measurements of blood Pb, yard soil Pb, residential interior dust Pb loading, first-draw water Pb, paint Pb assessment and other behavioral (i.e., hand-to-mouth activity, hygiene rating) and demographic variables (i.e., hygiene rating, poverty level, caregiver education). A multivariate regression model accounted for 34% of the observed variability in blood Pb. Yard soil Pb and interior dust Pb loading accounted for 10% and 3% of the blood Pb variability, respectfully. The regression model predicted a slope of 0.74 µg/dL blood Pb per ln[µg/g soil Pb] and a slope of 0.45 µg/dL blood Pb per ln[µg/ft^2] dust Pb loading.

4.6 Biokinetic Models of Pb Exposure-Blood Pb Relationships

An alternative to regression models are mechanistic models, which attempt to specify all parameters needed to describe the mechanisms (or processes) of transfer of Pb from the environment to human tissues. Such mechanistic models are more complex than regression models; this added complexity introduces challenges in terms of their mathematical solution and empirical verification. However, by incorporating parameters that can be expected to vary spatially or temporally, or across individuals or populations, mechanistic models can be extrapolated to a wide range of exposure scenarios, including those that may be outside of the domain of paired predictor-outcome data used to develop the model. Exposure-intake models, a type of mechanistic models, are highly simplified mathematical representations of relationships between levels of Pb in environmental

media and human Pb intakes (e.g., µg Pb ingested per day). These models include parameters representing processes of Pb transfer between environmental media (e.g., air to surface dust) and to humans, including rates of human contact with the media and intakes of the media (e.g., g soil ingested per day). Intake-biokinetic models provide the analogous mathematical representation of relationships between Pb intakes and Pb levels in body tissues (e.g., blood Pb concentration). Biokinetic models include parameters that represent processes of Pb transfer (a) from portals of entry into the body and (b) from blood to tissues and excreta. Linked together, exposure-intake and intake-biokinetics models (i.e., integrated exposure-intake-biokinetics models) provide an approach for predicting blood Pb concentrations (or Pb concentrations in other tissues) that corresponds to a specified exposure (medium, concentration, and duration). Detailed information on exposure and internal dose can be obtained from controlled experiments, but almost never from epidemiological observations or from public health monitoring programs. Exposure intake-biokinetics models can provide these predictions in the absence of complete information on the exposure history and blood Pb concentrations for an individual (or population) of interest. Therefore, these models are critical to applying epidemiologic-based information on blood Pb-response relationships to the quantification and characterization of human health risk. They are also critical for assessing the potential impacts of public health programs directed at mitigation of Pb exposure or of remediation of contaminated sites.

However, they are not without their limitations. Human exposure-biokinetics models include large numbers of parameters, which are required to describe the many processes that contribute to Pb intake, absorption, distribution, and elimination. The large number of parameters complicates the assessment of confidence in parameter values, many of which cannot be directly measured. Statistical procedures can be used to evaluate the degree to which model outputs conform to "real-world" observations and values of influential parameters can be statistically estimated to achieve good agreement with observations. Still, large uncertainty can be expected to remain about many, or even most, parameters in complex exposure-biokinetic models. Such uncertainties need to be identified and their impacts on model predictions quantified (i.e., sensitivity analysis or probabilistic methods).

Modeling of human Pb exposures and biokinetics has advanced considerably during the past several decades, although there have been relatively few developments since the 2006 Pb AQCD was published. Still in use is the *Integrated Exposure Uptake Biokinetic (IEUBK) Model for Lead in Children* (U.S. EPA, 1994) and models that simulate Pb biokinetics in humans from birth through adulthood (O'Flaherty, 1995; Leggett, 1993; O'Flaherty, 1993). The EPA AALM is still in development. A complete and extensive discussion of these models can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

4.7 Summary and Conclusions

4.7.1 Exposure

Exposure data considered in this assessment build upon the conclusions of the 2006 Pb AQCD (2006b), which found that air Pb concentrations in the U.S. and associated biomarkers of exposure to Pb have decreased substantially following reductions in industrial point sources of Pb, and restrictions on Pb in gasoline, house-hold paints, and solder. Pb exposure is difficult to assess because Pb has multiple sources in the environment and passes through various media. The atmosphere is the main environmental transport pathway for Pb, and, on a global scale, atmospheric Pb is primarily associated with fine particulate matter, which can deposit to soil and water. In addition to primary emission of particle-bearing or gaseous Pb to the atmosphere, Pb can be suspended to the air from soil or dust. Air-related pathways of Pb exposure are the focus of this assessment. In addition to inhalation of Pb from ambient air, air-related Pb exposure pathways include inhalation and ingestion of Pb from indoor dust and/or outdoor soil that originated from recent or historic ambient air (e.g., air Pb that has penetrated into the residence either via the air or tracking of soil), ingestion of Pb in drinking water contaminated from atmospheric deposition onto surface waters or from indirect surface runoff of deposition of ambient Pb, and ingestion of Pb in dietary sources after uptake by plants or grazing animals. Non-air-related Pb exposures may include occupational exposures, hand-to-mouth contact with Pb-containing consumer goods, hand-to-mouth contact with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes. Pb can cycle through multiple media prior to human exposure. Given the multitude of possible air-related exposure scenarios and the related difficulty of constructing Pb exposure histories, most studies of Pb exposure through air, water, and soil can be informative to this review. Other exposures, such as occupational exposures, contact with consumer goods in which Pb has been used, or ingestion of Pb in drinking water conveyed through Pb pipes may also contribute to Pb body burden.

A number of monitoring and modeling techniques have been employed for ambient Pb exposure assessment. Environmental Pb concentration data can be collected from ambient air Pb monitors, soil Pb samples, dust Pb samples, and dietary Pb samples to estimate human exposure. Exposure estimation error depends in part on the collection efficiency of these methods; collection efficiency for ambient air Pb FRM samplers is described in Section 3.4. Additionally, high spatial variability of the Pb concentrations in various media also can contribute to exposure error, as described in the 2009 PM ISA (U.S. EPA, 2009a). Models, such as the Integrated Exposure Uptake Biokinetic (IEUBK)

model, simulate human exposure to Pb from multiple sources and through various routes including inhalation, ingestion, and dermal exposure. IEUBK model inputs include soil Pb concentration, air Pb concentration, dietary Pb intake including drinking water, Pb dust ingestion, human activity, and biokinetic factors. Measurements and/or assumptions can be utilized when formulating the model inputs; errors in measurements and assumptions thus have the potential to propagate through the exposure models.

Section 4.1 presents data illustrating potential exposure pathways. Soil can act as a reservoir for deposited Pb emissions, and exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as shoe tracking and hand-to-mouth contact, which is the main pathway of childhood exposure to Pb. Airborne particles containing Pb tend to be small (much of the distribution <10 μm) compared with Pb in soil or dust particles (~50 μm to several hundred μm); Pb deposition to soil is described in Section 3.3. Hence, hand-to-mouth contact with Pb-bearing soil or dust and/or tracking Pb contaminated soil or dust into homes are more common means for human exposure to Pb. Infiltration of Pb dust into indoor environments has been observed, and Pb dust has been shown to persist in indoor environments even after repeated cleanings. Measurements of particle-bound Pb exposures reported in this assessment have shown that personal exposure measurements for Pb concentration are typically higher than indoor or outdoor ambient Pb concentrations.

4.7.2 Toxicokinetics

The majority of Pb in the body is found in bone (roughly 90% in adults, 70% in children); only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to red blood cells (RBCs). It has been suggested that the small fraction of Pb in plasma (<1%) may be the more biologically labile and toxicologically active fraction of the circulating Pb. The relationship between Pb in blood and plasma is pseudo-linear at relatively low daily Pb intakes (i.e., <10 μg/day/kg) and at blood Pb concentrations <25 μg/dL, and becomes curvilinear at higher blood Pb concentrations due to saturable binding to RBC proteins. As blood Pb level increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues.

The burden of Pb in the body may be viewed as divided between a dominant slow (i.e., uptake and elimination) compartment (bone) and smaller fast compartment(s) (soft tissues). Pb uptake and elimination in soft tissues is much faster than in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of exposure. During infancy and childhood, bone calcification is most active in trabecular

bone (e.g., patella); whereas, in adulthood, calcification occurs at sites of remodeling in cortical (e.g., tibia) and trabecular bone (Aufderheide and Wittmers, 1992). A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, in early childhood bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, much of the Pb acquired early in life is not permanently fixed in the bone.

The exchange of Pb from plasma to the bone surface is a relatively rapid process. Pb in bone becomes distributed in trabecular and the more dense cortical bone. The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80% cortical to 20% trabecular. Of the bone types, trabecular bone is more reflective of recent exposures than is cortical bone due to the slow turnover rate and lower blood perfusion of cortical bone. Some Pb diffuses to deeper bone regions where it is relatively inert, particularly in adults. These bone compartments are much more labile in infants and children than in adults as reflected by half-times for movement of Pb from bone into to the plasma (e.g., cortical half-time = 0.23 years at birth, 3.7 years at 15 years of age, and 23 years in adults; trabecular half-time = 0.23 years at birth, 2.0 years at 15 years of age, and 3.8 years in adults) (Leggett, 1993).

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood to maternal blood Pb ratios. Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL. Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton.

The dominant elimination phase of Pb kinetics in the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days. An abrupt change in Pb uptake gives rise to a relatively rapid change in blood Pb, to a new quasi-steady state, achieved in ~75-100 days (i.e., 3-4 times the blood elimination half-life). A slower phase of Pb clearance from the blood may become evident with longer observation periods following a decrease in exposure due to the gradual redistribution of Pb among bone and other compartments.

4.7.3 Pb Biomarkers

Overall, trends in blood Pb levels have been decreasing among U.S. children and adults over the past 20 years (Section 4.4). The median blood Pb level for the entire U.S. population is 1.2 µg/dL and the 95th percentile blood Pb level was 3.7 µg/dL, based on the 2007-2008 NHANES data (NCHS, 2010). Among children aged 1-5 years, the

median and 95th percentiles were slightly higher at 1.4 μg/dL and 4.1 μg/dL, respectively.

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines body burden and Pb in bone. The contribution of bone Pb to blood Pb changes depending on the duration and intensity of the exposure, age, and various other physiological stressors that may affect bone remodeling (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) beyond that which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. In adults and children, where exposure to Pb has effectively ceased or greatly decreased, a slow decline in blood Pb concentrations over the period of years is most likely due to the gradual release of Pb from bone. Bone Pb is an index of cumulative exposure and body burden. Even bone compartments should be recognized as reflective of differing exposure periods with Pb in trabecular bone exchanging more rapidly than Pb in cortical bone with the blood. This difference in the compartments makes Pb in cortical bone a better marker of cumulative exposure and Pb in trabecular bone more likely to be correlated with blood Pb, even in adults.

Sampling frequency is an important consideration when evaluating blood Pb and bone Pb levels in epidemiologic studies, particularly when the exposure is not well characterized. It is difficult to determine what blood Pb is reflecting in cross-sectional studies that sample blood Pb once, whether recent exposure or movement of Pb from bone into blood from historical exposures. In contrast, cross-sectional studies of bone Pb and longitudinal samples of blood Pb concentrations over time provide more of an index of cumulative exposure and are more reflective of average Pb body burdens over time. The degree to which repeated sampling will reflect the actual long-term time-weighted average blood Pb concentration depends on the sampling frequency in relation to variability in exposure. High variability in Pb exposures can produce episodic (or periodic) oscillations in blood Pb concentration that may not be captured with low sampling frequencies. Furthermore, similar blood Pb concentrations in two individuals (or populations), regardless of their age, do not necessarily translate to similar body burdens or similar exposure histories.

The concentration of Pb in urine follows blood Pb concentration, in that it mainly reflects the exposure history of the previous few months and therefore, is likely a relatively poor index of Pb body burden. There is added complexity with Pb in urine because concentration is also dependent upon urine flow rate, which requires timed urine samples

that is often not feasible in epidemiologic studies. Other biomarkers have been utilized to a lesser extent (e.g., Pb in teeth).

4.7.4 Air Lead-Blood Lead Relationships

The 1986 Pb AQCD (U.S. EPA, 1986a) described epidemiological studies of relationships between air Pb and blood Pb. Much of the pertinent earlier literature for child populations described in the 1986 Pb AQCD was also included in a meta-analysis by Brunekreef (1984). Based on the studies available at that time, the 1986 Pb AQCD concluded that "the blood Pb versus air Pb slope β is much smaller at high blood and air levels." This is to say that the slope β was much smaller for occupational exposures where high blood Pb levels (>40 μg/dL) and high air Pb levels (much greater than 10 $\mu g/m^3$) prevailed relative to lower environmental exposures which showed lower blood Pb and air Pb concentrations (<30 μg/dL and <3 $\mu g/m^3$). For those environmental exposures, it was concluded that the relationship between blood Pb and air Pb "…for direct inhalation appears to be approximately linear in the range of normal ambient exposures (0.1-2.0 $\mu g/m^3$)" (Chapter 1, pp 98 of the 1986 Pb AQCD). In addition to the meta-analysis of Brunekreef (1984), more recent studies have provided data from which estimates of the blood Pb-air Pb slope can be derived for children (Table 4-12). The range of estimates from these studies is 4-9 μg/dL per $\mu g/m^3$, which encompasses the estimate from the Brunekreef (1984) meta-analysis. Most studies have described the blood Pb-air Pb relationship as either log-log (Schnaas et al., 2004; Hayes et al., 1994; Brunekreef, 1984), which predicts an increase in the blood Pb-air Pb slope with decreasing air Pb concentration or linear (Hilts, 2003; Tripathi et al., 2001; Schwartz and Pitcher, 1989), which predicts a constant blood Pb-air Pb slope regardless of air Pb concentrations. These differences may simply reflect model selection by the investigators; alternative models are not reported in these studies. The blood Pb-air Pb slope may also be affected in some studies by the inclusion of parameters (e.g., soil Pb) that may account for some of the variance in blood Pb attributable to air Pb. Other factors that likely contribute to the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources, which varied among individual studies.

5 INTEGRATED HEALTH EFFECTS OF LEAD EXPOSURE

5.1 Introduction

This chapter summarizes, integrates, and evaluates the evidence for the broad spectrum of health effects associated with exposure to Pb. The chapter begins (Section 5.2) with a discussion of the evidence for the modes of action that mediate the health effects of Pb, including those modes of action that are shared by all of the health effects evaluated in this ISA and those modes of action that are specific to particular endpoints. Subsequent sections comprise evaluations of the epidemiologic and toxicological evidence for the effects of Pb exposure on health outcomes related to nervous system effects (Section 5.3), cardiovascular effects (Section 5.4), renal effects (Section 5.5), immune effects (Section 5.6), hematological effects (Section 5.7), and reproductive and developmental effects (Section 5.8). Section 5.9 reviews the evidence for the effects of Pb on other noncancer health outcomes, for which the cumulative bodies of evidence are smaller, including those related to the hepatic system (Section 5.9.1), gastrointestinal system (Section 5.9.2), endocrine system (Section 5.9.3), bone and teeth (Section 5.9.4), ocular health (Section 5.9.5), and respiratory system (Section 5.9.6). Chapter 5 concludes with a discussion of the evidence for Pb effects on cancer (Section 5.10).

Individual sections for major outcome categories (e.g., nervous system, cardiovascular, renal) begin with a brief summary of conclusions from the 2006 Pb AQCD (U.S. EPA, 2006c) followed by an evaluation of recent (i.e., published since the completion of the 2006 Pb AQCD) studies that is intended to build upon evidence from previous reviews. Within each of these sections, results are organized by endpoint (e.g., cognitive function, behavior, neurodegenerative diseases) then by specific scientific discipline (i.e., epidemiology, toxicology). This chapter evaluates evidence for both short- and long-term Pb exposures, which are defined as less than four weeks and greater than four weeks, respectively, in animal toxicological studies and less than one year and greater than one year, respectively, in epidemiologic studies (Section 2.1).

Sections for each of the major outcome categories (e.g., nervous system, cardiovascular, renal effects) conclude with an integrated summary of the evaluation of evidence and a conclusion regarding causality. Based upon the framework (described in the Preamble to this ISA), a determination of causality was made for a group of related endpoints within a major outcome category (e.g., cognitive function, attention-related behavioral problems). In judgments regarding causality, emphasis was placed on studies with relevant Pb exposure routes and concentrations in toxicological studies and internal dose measures in

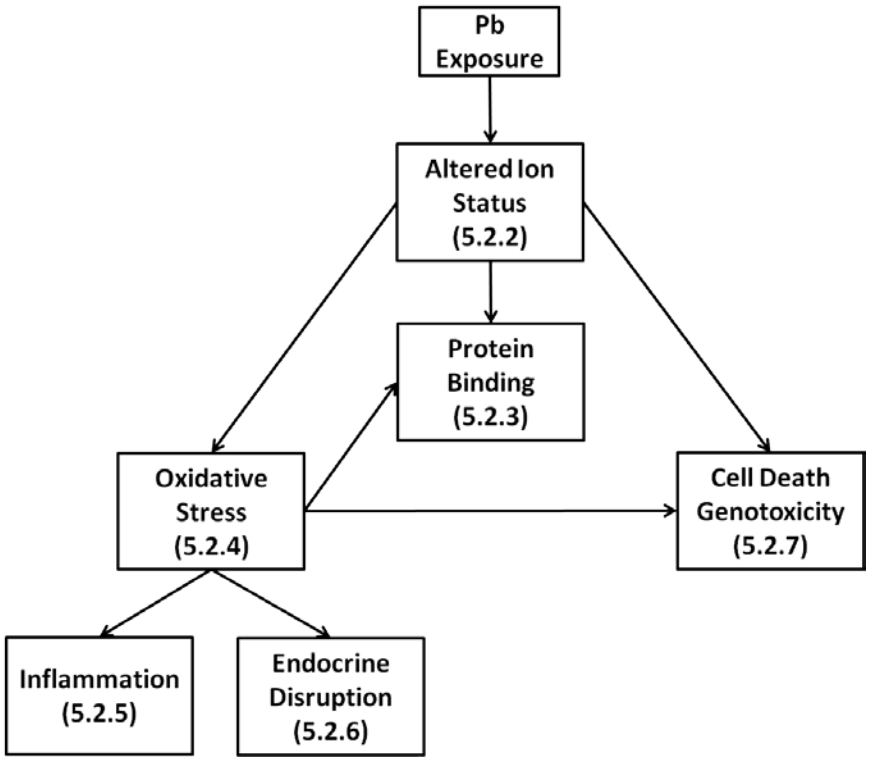
epidemiologic studies (generally one order of magnitude above blood Pb levels in the current U.S. population as described in Section 2.1). Studies that examined higher Pb concentrations were evaluated particularly to inform mode of action. Further, evidence was evaluated for consistency of findings across multiple studies and the extent to which chance, confounding (i.e., bias due to a correlation with Pb biomarker level and causal association with the outcome), and other biases could be ruled out with reasonable confidence. Such evidence included high quality epidemiologic studies with representative population-based groups or samples, prospective versus cross-sectional or ecologic design; rigorous statistical analysis (i.e., multivariate regression) with assessment of potential confounding factors; information on the concentration-response relationship; and supporting toxicological evidence. The extent of consideration for potential confounding varied among epidemiologic studies. Because no single study considered all potential confounding factors, and not all potential confounding factors were examined in the collective body of evidence, residual confounding by unmeasured factors is possible. However, the examination of factors well documented in the literature to be associated with Pb exposure and health outcomes and supporting toxicological evidence help to minimize the undue influence of confounding bias on the observed epidemiologic associations. The biological plausibility provided by the coherence of evidence between toxicology and epidemiology and across a spectrum of related endpoints, including evidence for modes of action, was used as support to address uncertainties in the epidemiologic evidence due to biases from factors such as selective publication, recruitment or participation of subjects; reverse causality; or confounding.

5.2 Modes of Action

5.2.1 Introduction

The diverse health effects associated with Pb exposure are dependent on multiple factors, including the concentration and duration of exposure, the particular Pb compounds constituting the exposure, and which tissues are affected. Pb exposure is linked to downstream health effects by various modes of action. A mode of action (MOA) is the common set of biochemical, physiological, or behavioral responses (i.e., empirically observable precursor steps) that can cumulatively result in the formation of negative health outcomes. Although the effects of Pb exposure appear to be mediated through multiple modes of action, alteration of cellular ion status (including disruption of calcium homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) seems to be the major unifying mode of action underlying all subsequent modes of action (Figure 5-1). This section draws information

from all of the subsequent health effects sections in Chapter 5, and identifies the major modes of action operating at the molecular, cellular, and tissue/organ level. In turn, the individual health effect sections bridge these MOA effects to those observed on the organismal level. Each of the individual health effect sections includes a more detailed description of the mechanisms specific to the individual health effect. Accordingly, this section differs in structure and content from other health effects sections as it does not primarily focus on the literature published since the 2006 Pb AQCD, but rather incorporates recent information with earlier studies (which together represent the current state of the science) on the possible modes of action of Pb. Higher concentrations of Pb are often utilized in mode of action studies. This section includes some studies that are conducted at concentrations greater than one order of magnitude above the upper end of the blood Pb distribution of the general U.S. population when it is likely that the mode of action does not differ at higher concentrations.



Note: The subsections where these MOAs are discussed are indicated in parentheses. (Section 5.2.2; Section 5.2.3; Section 5.2.4; Section 5.2.5; Section 5.2.6; and Section 5.2.7).

Figure 5-1 Schematic representation of the relationships between the various MOAs by which Pb exposure exerts its health effects.

5.2.2 Altered Ion Status

Physiologically-relevant metal ions (e.g., Ca^{2+}, Mg, Zn, Fe) are known to have a multitude of functions in biological systems, including roles as charge carriers, intermediates in enzymatically-catalyzed reactions, and structural elements in the proper maintenance of tertiary protein conformations (Garza et al., 2006). It is through disruption of these biological functions that Pb exerts its negative actions, ultimately interfering with such tightly regulated processes as cell signaling, intracellular ion homeostasis, ion transport, energy metabolism, and enzymatic function.

5.2.2.1 Disruption of Ca^{2+} Homeostasis

Calcium (Ca^{2+}) is one of the most important carriers of cell signals and regulates virtually all aspects of cell function, including energy metabolism, signal transduction, hormonal regulation, cellular motility, and apoptosis (Carafoli, 2005). Ca^{2+} homeostasis is maintained through a tightly regulated balance of cellular transport and intracellular storage (Pentyala et al., 2010). Disruption of Ca^{2+} homeostasis by Pb has been observed in a number of different cell types and cell-free environments, indicating that this is a major mode of action for Pb-induced toxicity on a cellular level.

Ca^{2+} homeostasis is particularly important in bone cells, as the skeletal system serves as the major dynamic reservoir of Ca^{2+} in the body (Wiemann et al., 1999; Long et al., 1992). Bone cells also are unique in that they exist in a microenvironment that is high in Ca^{2+}, and potentially high in Pb concentrations. This may increase their relative exposure to Pb and thus Pb-induced effects (Long et al., 1992). A series of studies from the laboratory of Long, Dowd, and Rosen have indicated that exposure of cultured osteoblastic bone cells to Pb alters intracellular Ca^{2+} levels ($[Ca^{2+}]_i$). Exposure of osteoblasts to 1, 5, or 25 µM Pb for 40-300 minutes resulted in prolonged increases in $[Ca^{2+}]_i$ of 36, 50 and 120% over baseline, respectively (Schanne et al., 1997; Schanne et al., 1989). Long et al. (1992) observed that exposure of osteoblasts to either 400 ng parathyroid hormone (PTH)/mL culture medium for 1 hour or 25 µM Pb for 20 hours increased $[Ca^{2+}]_i$. Pb-exposed cells pretreated with PTH increased $[Ca^{2+}]_i$ above concentrations observed in either single exposure (Pb alone or PTH alone), indicating that Pb may disrupt the ability of bone cells to respond to normal hormonal control. A similar increase in $[Ca^{2+}]_i$ was also observed when bone cells were co-treated with epidermal growth factor (EGF, 50 ng/mL) plus Pb (5 µM), versus EGF alone (Long and Rosen, 1992). Pb-induced increases in $[Ca^{2+}]_i$ were blocked by a protein kinase C (PKC) inhibitor, indicating that PKC activation may serve as one mechanism by which Pb perturbs $[Ca^{2+}]_i$ (Schanne et al., 1997). Schirrmacher et al. (1998) also observed

alterations in Ca^{2+} homeostasis in osteoblasts exposed to 5 µM Pb for 50 minutes due to potential disruption of Ca^{2+}ATPases. However, Wiemann et al. (1999) demonstrated that exposure to 5 or 12.5 µM Pb inhibited the Ca^{2+}-release-activated calcium influx of Ca^{2+} independently of any inhibitory effect on Ca^{2+}ATPases.

Ca^{2+} homeostasis has also been shown to be disturbed in erythrocytes exposed to Pb (Quintanar-Escorza et al., 2010; Quintanar-Escorza et al., 2007; Shin et al., 2007). In blood samples taken from Pb-exposed workers (mean [SD] blood Pb level: 74.4 [21.9] µg/dL), the $[Ca^{2+}]_i$ was approximately 2.5-fold higher than that seen in nonexposed workers (mean [SD] blood Pb level: 9.9 [2.0] µg/dL) (Quintanar-Escorza et al., 2007). The increase in $[Ca^{2+}]_i$ was associated with higher osmotic fragility and modifications in erythrocyte shape. In a separate investigation, when erythrocytes from 10 healthy volunteers were exposed (in vitro) at concentrations of 0.2 to 6.0 µM Pb for 24 or 120 hours, concentration-related increases in $[Ca^{2+}]_i$ were observed across all concentrations for both durations of exposure (Quintanar-Escorza et al., 2010). Subsequent exposures of erythrocytes to either 0.4 or 4.0 µM Pb [corresponding to 10 or 80 µg/dL in exposed workers (Quintanar-Escorza et al., 2007)] for 12-120 hours resulted in duration-related increases with durations >12 hours. Osmotic fragility (measured as percent hemolysis) was increased in erythrocytes exposed to 0.4 µM Pb for 24 hours. Co-incubation with a vitamin E analog mitigated these effects, indicating that the increase in $[Ca^{2+}]_i$ is dependent on the oxidative state of the erythrocytes. Shin et al. (2007) observed that incubation of human erythrocytes with 5 µM Pb for 1 hour resulted in a 30-fold increase in $[Ca^{2+}]_i$ in vitro, inducing the pro-coagulant activity of exposed erythrocytes. Induction of pro-coagulant activity in erythrocytes could lead to thrombus formation and negatively contribute to overall cardiovascular health; whereas increased osmotic fragility could substantially reduce erythrocyte life span and ultimately lead to anemic conditions.

Similar to effects seen in erythrocytes, Pb has been observed to interfere with Ca^{2+} homeostasis in platelets and white blood cells. Dowd and Gupta (1991) observed that 1 µM Pb (for 3.5 hours) was the lowest exposure concentration to result in increases in $[Ca^{2+}]_i$ in human platelets (in vitro). The observed increase in $[Ca^{2+}]_i$ levels was attributed to the increased influx of external Ca^{2+}, possibly through ligand-gated Ca^{2+} channels. In mouse splenic lymphocytes, 1 µM Pb was the lowest exposure concentration found to increase $[Ca^{2+}]_i$, with incubation periods of 10 minutes or greater (Li et al., 2008c). These increases in $[Ca^{2+}]_i$ appeared to be reversible as $[Ca^{2+}]_i$ returned to baseline after one hour. Pretreatment with a calmodulin antagonist slightly mitigated the effects of Pb exposure, indicating a role for calmodulin in disruption of Ca^{2+} homeostasis by Pb exposure in lymphocytes. In rat tail arteries exposed to 1.2 µM Pb acetate for 1 hour, $[Ca^{2+}]_i$ increased over controls, possibly through increased transmembrane influx of external Ca^{2+} (Piccinini et al., 1977).

Exposure of the microsomal fraction (prepared from rat brain cells) to as little as 0.25 µM Pb for 2 minutes resulted in increased release of Ca^{2+} into the culture medium (Pentyala et al., 2010). Further, Pb exposure also decreased the activity of microsomal Ca^{2+}ATPase, thus decreasing the sequestration of Ca^{2+} into microsomes. The results of this study suggest that disruption of microsomal release and re-uptake of Ca^{2+} may alter Ca^{2+} homeostasis, ultimately leading to altered signal transduction and neuronal dysfunction. However, Ferguson et al. (2000) observed that $[Ca^{2+}]_i$ was decreased in rat hippocampal neurons in response to exposure to 0.1 µM Pb for 1-48 hours; although the observed decreases were not time-dependent. The decrease in $[Ca^{2+}]_i$ was shown to be due to increased efflux of Ca^{2+} out of the neuron via a calmodulin-regulated mechanism, possibly through stimulated Ca^{2+} efflux via Ca^{2+}ATPase.

Pb exposure has been shown to disrupt $[Ca^{2+}]_i$ levels in multiple cell types including osteoblasts, erythrocytes, platelets, and neuronal cells. This alteration in Ca^{2+} homeostasis could potentially affect cell signaling and disrupt the normal physiological function of these cells.

5.2.2.2 Disruption of Ion Transport Mechanisms

As described above, deregulation of Ca^{2+} homeostasis can result in negative effects in multiple organ systems. Under normal conditions in the life cycle of most cells, cytosolic concentrations of free Ca^{2+} fluctuate between approximately 100 to 200 nM and Ca^{2+} that has entered the cell must be removed in order to maintain normal homeostatic concentrations (Carafoli, 2005). An important component in the maintenance of Ca^{2+} homeostasis is transmembrane transport of Ca ions via Ca^{2+}ATPase and voltage-gated Ca^{2+} channels (Carafoli, 2005). Pb has been shown to disrupt the normal movement of Ca^{2+} ions, as well as other physiologically important ions through interactions with these transport mechanisms.

Multiple studies have reported alterations in the activity of Na^+/K^+ATPase, Ca^{2+}ATPase, and Mg^{2+}ATPases after Pb exposure in animal models. Decreases in the activity of all three ATPases were observed in the kidneys and livers of rats exposed to 750 ppm Pb in drinking water for 11 weeks (mean [SD] blood Pb level: 55.6 [6.3] µg/dL) (Kharoubi et al., 2008a) and in erythrocytes from rats exposed to 2,000 ppm Pb in drinking water for 5 weeks (mean [SD] blood Pb level: 97.56 [11.8] µg/dL) (Sivaprasad et al., 2003). Increases in lipid peroxidation were seen in both studies, and the decrements in ATPase activities may be explained by generation of free radicals in Pb-exposed animals. A decrease in the activity of Na^+/K^+ATPase was observed in rabbit kidney membranes exposed to 0.01 to 10 µM Pb, possibly due to Pb inhibiting the hydrolytic cleavage of

phosphorylated intermediates in the K-related branch of the pump (Gramigni et al., 2009). Similar decreases in Na^+/K^+ATPase activity were observed in brain synaptosomes isolated from rats that were exposed to 200 ppm Pb in drinking water for 3 months (blood Pb level: 37.8 µg/dL) (Rafalowska et al., 1996) or 15 mg Pb/kg injected (i.p.) for 7 days (blood Pb level: 112.5 µg/dL) (Struzynska et al., 1997a). Inhibition of Na^+/K^+ATPase activity was also observed in primary cerebellar granule neuronal cultures obtained from rat pups that were pre- and post-natally (to PND8) exposed to Pb (1,000 ppm Pb acetate in dams' drinking water, resulting in blood Pb level of 4 µg/dL) (Baranowska-Bosiacka et al., 2011b). The activity of Ca^{2+}ATPase in the sarcoplasmic reticulum of rabbits exposed to 0.01 µM Pb was similarly decreased (Hechtenberg and Beyersmann, 1991). The inhibitory effect of Pb was diminished in the presence of high Mg-ATP concentrations. The activity of generic ATPase was reported to be altered in the testes of rat pups exposed to 300 ppm (mg/L) Pb acetate, both during lactation and in drinking water after weaning to the age of 6, 8, 10, or 12 weeks (Liu et al., 2008). In pregnant rats fed a Pb-depleted (20 ± 5 µg/kg) or control (1 mg/kg) diet during gestation and lactation, no difference was observed in the activity of Na^+/K^+ATPase and Ca^{2+}/Mg^{2+}ATPase in the parental generation (Eder et al., 1990). However, the offspring (exposed via placental and lactational transfer of Pb) of Pb-depleted rats displayed decreased activities in both enzymes compared with offspring of rats with higher Pb exposures. An increase in the Na^+/K^+ATPase activity was observed in rats treated (i.p.) with 20 mg/kg Pb for 14 consecutive days (Jehan and Motlag, 1995). Co-exposure of Pb with Zn and Cu greatly attenuated the increase in ATPase activity. Although the precise mechanism was not investigated, Navarro-Moreno et al. (2009) reported that Ca^{2+} uptake was diminished in proximal renal tubule cells in rats chronically exposed to 500 ppm Pb in drinking water for 7 months (mean [SD] blood Pb level: 43.0 [7.6] µg/dL).

In vitro studies of ATPase activities in human erythrocyte ghosts have also shown that Pb affects the transport of metal ions across membranes. Calderon-Salinas et al. (1999a) observed that 1-5 × 10^3 µM Pb and Ca^{2+} were capable of inhibiting the passive transport of each other in human erythrocyte ghosts incubated with both cations. Subsequent inhibition experiments indicated that both cations share the same electrogenic transport pathway (Sakuma et al., 1984). Further study by this group (Calderón-Salinas et al., 1999b) demonstrated that Pb can noncompetitively block the transport of Ca^{2+} by inhibiting the activity of Ca^{2+}/Mg^{2+}ATPase at concentrations of 1-5 × 10^3 µM. Mas-Oliva (1989) demonstrated that the activity of Ca^{2+}/Mg^{2+}ATPase in human erythrocyte ghosts was inhibited by incubation with 0.1-100 µM Pb. The inhibitory action was most likely due to direct reaction with sulfhydryl groups on the ATPase enzyme at Pb concentrations greater than 1 µM, but due to the action of Pb on calmodulin at lower concentrations. Grabowska and Guminska (1996) observed that 10 µg/dL was the lowest Pb concentration to decrease the activity of Na^+/K^+ATPase in erythrocyte ghosts; activity

of Ca^{2+}/Mg^{2+}ATPase was less sensitive to Pb exposure, and Mg^{2+}ATPase activity was not affected.

Effects on ATPase activity are also observed in association with blood Pb levels in human populations. In a study investigating ATPase activities in Pb-exposed workers in Nigeria, Abam et al. (2008) observed that the activity of erythrocyte membrane-bound Ca^{2+}/Mg^{2+}ATPase was decreased by roughly 50% in all occupational groups (range of mean [SD] blood Pb level across nine occupational groups: 28.75 [11.31] to 42.07 [12.01] µg/dL) compared to nonexposed controls (mean [SD] blood Pb level: 12.34 [2.44] in males and 16.85 [6.01] µg/dL in females). Higher membrane concentrations of Ca^{2+} and Mg^{2+} were also observed, indicating that Pb prevented the efflux of those cations from the cell, most likely by substituting for those metals in the active site of the ATPase. In a study of 247 mother-newborn pairs, Campagna et al. (2000) observed that newborn (cord) blood Pb (geometric mean [5th-95th percentile]: 4.8 [2.8-9.2] µg/dL) was negatively and significantly associated with maternal blood Ca^{2+} pump activities; however, newborn (cord) blood Pb was not significantly associated with newborn (cord) blood Ca^{2+} pump activities. Newborn hair Pb (geometric mean [5th-95th percentile]: 1.1 [0.1-8.0] µg/g) was negatively and significantly associated with both maternal and newborn (cord) blood Ca^{2+} pump activities. In a population of 81 newborns, Huel et al. (2008) found that newborn hair and newborn (cord) blood Pb levels (mean [SD] newborn hair Pb and newborn [cord] blood Pb levels: 1.22 [1.41] µg/g and 3.54 [1.72] µg/dL) were negatively associated with Ca^{2+}ATPase activity in plasma membranes of erythrocytes isolated from newborn (cord) blood; newborn hair Pb levels were more strongly associated with newborn (cord) Ca^{2+} pump activity than were newborn (cord) blood Pb levels.

Pb has also been shown to disrupt cation transport mechanisms through direct action on voltage-gated cation channels. Audesirk and Audesirk (1993, 1991) demonstrated that extracellular free Pb inhibits the action of multiple voltage-gated Ca^{2+} channels, with free Pb IC_{50} (half maximal inhibitory concentration) values of 0.7 µM for L-type channels and 1.3 µM for T-type channels in neuroblastoma cells maintained in culture media, and IC_{50} values as low as 0.03 µM for L-type channels in cultured hippocampal neurons. Sun and Suszkiw (1995) corroborated the inhibitory action of extracellular Pb on voltage-gated Ca^{2+} channels, demonstrating an IC_{50} value of 0.3 µM in bovine adrenal chromaffin cells. The observed disruption of the voltage-gated Ca^{2+} channels most likely reflects competition between Pb and Ca^{2+} for the extracellular Ca^{2+} binding domain of the channel. Research by other laboratories supported these findings: Pb inhibited the action of multiple Ca^{2+} channels in human embryonic kidney cells transfected with L-, N-, and R-type channels (IC_{50} values of 0.38 µM, 1.31 µM, and 0.10 µM, respectively) (Peng et al., 2002) and P-type channels in cultured hippocampal neurons at concentrations up to

3 µM (Ujihara et al., 1995). However, in bovine adrenal chromaffin cells, intracellular Pb was observed to enhance Ca^{2+} currents through attenuation of the Ca^{2+} dependent deactivation of Ca^{2+} channels at an EC_{50} value of 200 µM, possibly through blocking the intracellular Ca^{2+} binding domain, or through Ca^{2+} dependent dephosphorylation of the channel (Sun and Suszkiw, 1995). Recently, Pb has also been shown to enter cells (HEK293, HeLa, and PC12 cell lines) through store-operated Ca^{2+} channels (Chiu et al., 2009; Chang et al., 2008b). In particular, the Orai1-STIM1 complex was shown to be critical in the entry of Pb ions into cells, and increased Pb permeation was directly related to decreased $[Ca^{2+}]_i$ concentrations at exposure concentrations as low as 0.1 µM.

Pb also has been found to disrupt the action of Ca^{2+}-dependent K^+ channels. Alvarez et al. (1986) observed that Pb promoted the efflux of K^+ from inside-out erythrocyte vesicles in a concentration-dependent manner at concentrations of 1-300 µM, either through action on a Mg^{2+} modulatory site or through direct interaction with the Ca^{2+} binding site. Fehlau et al. (1989) also demonstrated Pb-induced activation of the K^+ channel in erythrocytes. However, Pb only activated the K^+ channels at concentrations below 10 µM; higher concentrations of Pb completely inhibited channel activity, indicating the modulation of K^+ permeability is due to concentration dependent alterations in channel gating. Silken et al. (2001) observed that Pb activated K^+ channels in erythrocytes from the marine teleost *Scorpaena porcu*s in a concentration-dependent manner after a 20-minute incubation; minor loss of K^+ was seen at Pb concentrations of 1-2 µM, whereas exposure to 20-50 µM Pb resulted in approximately 70% K^+ loss. Competitive and inhibitory binding assays suggest that Pb directly activates K^+ channels in *S. porcus*.

Disruption of Neurotransmitter Release

Pb has been shown to inhibit the evoked release of neurotransmitters by inhibiting Ca^{2+} transport through voltage-gated channels in in vitro experiments (Cooper and Manalis, 1984; Suszkiw et al., 1984). However, in these same experiments, concentrations of Pb $\geq$ 5 µM were also observed to actually increase the spontaneous release of neurotransmitters. Subsequent research by other groups affirmed that Pb demonstrates Ca^{2+}-mimetic properties in enhancing neurotransmitter release from cells in the absence of Ca^{2+} and Ca^{2+}-induced depolarization. Tomsig and Suszkiw (1993) reported that Pb exposure induced the release of norepinephrine (NE) from bovine adrenal chromaffin cells, and was considerably more potent (as measured by half-maximal metal-dependent release [$K_{0.5}$]) than was Ca^{2+} ($K_{0.5}$ of 4.6×10^{-3} µM for Pb versus 2.4 µM for Ca^{2+}). Activation of PKC was observed to enhance the Pb-induced release of NE (Tomsig and Suszkiw, 1995). Westerink and Vijverberg (2002) observed that Pb acted as a high affinity substitute for Ca^{2+}, and triggered enhanced catecholamine release from PC12 cells at 10 µM in intact cells and 0.03 µM in permeabilized cells. The suppression of

Ca^{2+}-evoked release of neurotransmitters combined with the ability of Pb to enhance spontaneous releases could result in higher noise observed in the synaptic transmission of nerve impulses in Pb-exposed animals.

In rats exposed to Pb at concentrations of 1,000–10,000 ppm in drinking water beginning at gestational days GD15-GD16 and continuing to postnatal days PND120, decreases in total K^+-stimulated hippocampal gamma aminobutyric acid (GABA) release were seen at exposure levels of 1,000–5,000 ppm (range of mean [SD] blood Pb levels: 26.8 [1.3] - 61.8 [2.9] µg/dL) (Lasley and Gilbert, 2002). Maximal effects were observed at 2,000 ppm Pb in drinking water, but effects were less evident at 5,000 ppm, and were absent at 10,000 ppm. In the absence of Ca^{2+}, K^+-induced GABA release was increased with the two highest Pb exposure concentrations, suggesting a Pb-induced enhancement of K^+-evoked release of GABA. The authors suggest that this pattern of response indicates that Pb is a potent suppressor of K^+-evoked release at low concentrations, but a Ca^{2+} mimic in regard to independently inducing exocytosis and evoking neurotransmitter release at higher concentrations (Lasley and Gilbert, 2002). Suszkiw (2004) reports that augmentation of spontaneous release of neurotransmitters may involve Pb-induced activation of CaMKII-dependent phosphorylation of synapsin I or direct activation of synaptotagmin I. Further, Suszkiw (2004) suggests that unlike the intracellularly mediated effects of Pb on spontaneous release of neurotransmitters, Pb-induced inhibition of evoked transmitter releases is largely due to extracellular blockage of the voltage-gated Ca^{2+} channels.

In summary, Pb has been shown to disrupt ion transport mechanisms in toxicological and epidemiologic studies. Specific mechanisms disrupted include various cation-specific ATPases and voltage-gated cation channels. Alterations in ion transport functions have also been shown to disrupt neurotransmitter release in both in vivo and in vitro experiments.

5.2.2.3 Displacement of Metal Ions and Perturbed Protein Function

The binding of metal ions to proteins causes specific changes in protein shape, and these conformational changes may alter specific cellular function of many proteins (Kirberger and Yang, 2008). Metal binding sites on proteins are generally ion-specific and are influenced by multiple factors, including binding geometries, ligand preferences, ionic radius, and metal coordination numbers (Kirberger and Yang, 2008; Garza et al., 2006). The coordination chemistry that normally regulates metal-protein binding makes many proteins particularly susceptible to perturbation from Pb, as it is able to function with

flexible coordination numbers and can bind multiple ligands (Kirberger and Yang, 2008; Garza et al., 2006). However, due to differences in its physical properties, Pb induces abnormal conformational changes when it binds to proteins (Kirberger and Yang, 2008; Bitto et al., 2006; Garza et al., 2006; Magyar et al., 2005), and these structural changes elicit altered protein function. It is known that $[Ca^{2+}]_i$ is an important second messenger in cell signaling pathways, and operates by binding directly to and activating proteins such as calmodulin and PKC (Goldstein, 1993). Alterations in the functions of both of these proteins due to direct interaction with Pb have been well documented in the literature.

PKC is a family of serine/threonine protein kinases critical for cell signaling and important for cellular processes, including growth and differentiation (Goldstein, 1993). PKC contains a "C2" Ca^{2+}-binding domain and requires binding of the cation, as well as the presence of diacylglycerol and phospholipids, for proper cellular activity (Garza et al., 2006). Markovac and Goldstein (1988b) observed that, in the absence of Ca^{2+}, exposure to 10^{-6} µM concentrations of Pb for 5 minutes directly activated PKC purified from rat brains. The activation of PKC by Pb was more potent than was Ca^{2+}-dependent activation by five orders of magnitude. Long et al. (1994) affirmed these findings, reporting that Pb had a K_{act} 4,800 times smaller than that of Ca^{2+} (5.5×10^{-5} µM versus 25 µM, following a 3 minute exposure). However, Ca^{2+} had a higher maximal activation of PKC than did Pb. This possibly indicates the presence of multiple Ca^{2+}-binding sites on the protein, and that Pb may bind the first site more efficiently than does Ca^{2+}, but not subsequent sites. Tomsig and Suszkiw (1995) further demonstrated the ability of Pb to activate PKC in bovine adrenal chromaffin cells incubated with 10^{-6} µM concentrations of Pb for 10 minutes but also reported that activation of PKC by Pb was only partial (approximately 40% of the maximum activity induced by Ca^{2+}) and tended to decrease at concentrations $>1 \times 10^{-3}$ µM.

Contrary to the above findings, Markovac and Goldstein (1988a) observed that Pb and Ca^{2+} activated PKC at equivalent concentrations and efficacies when broken cell preparations of rat brain microvessels were incubated with either cation for 45 minutes. However, when PKC activation was investigated in whole vessel preparations, no activation was observed, but PKC did become redistributed from the cytosolic to the particulate fraction after centrifugation. This suggests that Pb redistributes PKC at µM concentrations, but does not activate the protein in brain microvessels. In human erythrocytes exposed to Pb acetate for 60 minutes, the amount of PKC found in erythrocyte membranes and total PKC activity was increased at concentrations greater than 0.1 µM (Belloni-Olivi et al., 1996). The observation that neither Ca^{2+} nor diacylglycerol concentrations were increased due to Pb exposure, indicates that Pb-induced activation of PKC is due to direct interaction with the protein. Pb-induced

alterations in PKC have also been observed in other tissues, including increased activity in rabbit mesenteric arteries at 10^{-6} µM concentrations of Pb (Watts et al., 1995; Chai and Webb, 1988) and human erythrocytes from Pb-exposed workers (range of blood Pb levels: 5.4 to 69.3 µg/dL) (Hwang et al., 2002), and decreased activity in mouse macrophages and the rat brain cortex at µM concentrations (Murakami et al., 1993; Lison et al., 1990).

Calmodulin is another important protein essential for proper Ca^{2+}-dependent cell signaling. Calmodulin contains an "EF-hand" Ca^{2+} binding domain, which is dependent on the cation for proper activity (Garza et al., 2006). Calmodulin regulates events as diverse as cellular structural integrity, gene expression, and maintenance of membrane potential (Vetter and Leclerc, 2003; Saimi and Kung, 2002). Habermann et al. (1983) observed that exposure to Pb altered numerous cellular functions of calmodulin, including activation of calmodulin-dependent phosphodiesterase activity after 10 minutes incubation (minimal activation at 0.1 µM, EC_{50} = 0.5-1.0 µM), stimulation of brain membrane phosphorylation at Pb concentrations greater than 0.4 µM after 1 minute incubation, and increased binding of calmodulin to brain membranes at Pb concentrations greater than 1 µM after 10 minutes incubation. Habermann et al. (1983) reported that the affinity of Pb for Ca^{2+}-binding sites on calmodulin was approximate to that of Ca^{2+} itself (K_d ~20 µM), whereas Richardt et al. (1986) observed that Pb was slightly more potent than Ca^{2+} was at binding calmodulin (IC_{50} = 11 and 26 µM, respectively). Both studies indicated that Pb was much more effective at binding to calmodulin than was any other metal cation investigated (e.g., Hg, Cd, Fe). Kern et al. (2000) observed that Pb was more potent in binding to, and affecting conformational changes in, calmodulin compared to Ca^{2+} (EC_{50} values of 4-5.5 × 10^{-4} µM [threshold = 1 × 10^{-4} µM] and 0.45-0.5 µM [threshold = 0.1 µM], respectively). Pb, in the absence of Ca^{2+}, was also observed to activate calmodulin-dependent cyclic nucleotide phosphodiesterase activity at much lower concentrations compared to Ca^{2+} (EC_{50} value 4.3 × 10^{-4} µM [threshold = 3 × 10^{-4} µM] versus EC_{50} 1.2 × 10^{-3} µM [threshold = 0.2 µM; 50 minute incubation]). When incubated with physiological concentrations of Ca^{2+}, Pb induced phosphodiesterase activity at concentrations as low as 5 × 10^{-5} µM. Pb activated calcineurin, a Ca^{2+}-dependent phosphatase with widespread distribution in the brain and immune system, at threshold concentrations as low as 2 × 10^{-5} µM in the presence of Ca^{2+} (incubation time = 30 minutes), but inhibited its activity at concentrations greater than 2 × 10^{-4} µM (Kern and Audesirk, 2000). Thus, 10^{-6} µM concentrations of intracellular Pb appear to amplify the activity of calmodulin and thus can be expected to alter intracellular Ca^{2+} signaling in exposed cells (Kern et al., 2000). Mas-Oliva (1989) observed that low-exposure (<1 µM, 20 minute incubation) stimulatory effects of Pb exposure on the activity of Ca^{2+}/Mg^{2+}ATPase was due to Pb binding to calmodulin and subsequent activation of the ion pore. Ferguson et al. (2000) observed that exposure of rat

hippocampal neurons to Pb for 1 to 48 hours resulted in increased activation of a calmodulin-dependent Ca^{2+} extrusion mechanism.

Pb has also been observed to alter the activity of other proteins that rely on Ca^{2+} binding for normal cellular function. Osteocalcin is a matrix protein important in bone resorption, osteoclast differentiation, and bone growth; and has three Ca^{2+}-binding sites (Dowd et al., 2001). Incubation of osteocalcin in solution with Ca^{2+} and Pb resulted in the competitive displacement of Ca^{2+} by Pb (Dowd et al., 1994). Pb was found to bind to osteocalcin more than 1,000 times more tightly than was Ca^{2+} ($K_d = 1.6 \times 10^{-2}$ µM versus 7.0 µM, respectively), and analysis with nuclear magnetic resonance (NMR) indicated that Pb induced similar, though slightly different, secondary structures in osteocalcin, compared to Ca^{2+}. The authors hypothesized that the observed difference in Pb-bound osteocalcin structure may explain previous findings in the literature that Pb exposure reduced osteocalcin adsorption to hydroxyapatite (Dowd et al., 1994). Further research by this group also found that Pb binded osteocalcin approximately 10,000-times more tightly than did Ca^{2+} ($K_d = 8.5 \times 10^{-2}$ µM versus 1.25×10^{3} µM, respectively) (Dowd et al., 2001). However, the authors reported that Pb exposure actually caused increased hydroxyapatite adsorption at concentrations 2-3 orders of magnitude lower than that seen with Ca^{2+}. Additionally, Pb can displace Ca^{2+} in numerous other Ca^{2+}-binding proteins, such as proteins important in muscle contractions, renal Ca^{2+} transport and neurotransmission, including troponin C, parvalbumin, CaBP I and II, phospholipase A_2, and synaptotagmin I, at concentrations as low as the 10^{-3} µM range (Bouton et al., 2001; Osterode and Ulberth, 2000; Richardt et al., 1986).

Pb can displace metal cations other than Ca^{2+} that are requisite for protein function. One of the most researched targets for molecular toxicity of Pb is the second enzyme in the heme synthetic pathway, aminolevulinic acid dehydratase (ALAD). ALAD contains four Zn-binding sites and all four need to be occupied to confer full enzymatic activity (Simons, 1995). ALAD has been identified as the major protein binding target for Pb in human erythrocytes (Bergdahl et al., 1997a), and blood Pb levels are associated with inhibition of the enzyme in the erythrocytes of Pb-exposed workers and adolescents (blood Pb levels >10 µg/dL) (Ahamed et al., 2006; Ademuyiwa et al., 2005b), in lysed human erythrocytes exposed to Pb in vitro for 60 minutes ($K_i = 7 \times 10^{-6}$ µM) (Simons, 1995), and in rats exposed to 25 mg/kg Pb once a week for 4 weeks (mean [SD] blood Pb level: 6.56 [0.98] µg/dL) (Lee et al., 2005). Additional experiments indicated that lower concentrations of Zn result in greater inhibition of enzyme activity by Pb, suggesting a competitive inhibition between Zn and Pb at a single site (Simons, 1995).

Zn-binding domains are also found in transcription factors and proteins necessary for gene expression, including GATA proteins and transcription factors TFIIIA, Sp1, and

Erg-1 (Ghering et al., 2005; Huang et al., 2004; Reddy and Zawia, 2000; Hanas et al., 1999; Zawia et al., 1998). Pb was found to form tight complexes with the cysteine residues in GATA proteins (Pb stoichiometric stability constant ($^{CF}\beta_1^{Pb}$) = 6.4 (± 2.0)× 10^9 M^{-1} for single C-terminal GATA Zn finger from chicken and $^{DF}\beta_2^{Pb2}$ = 6.3 (± 6.3) × 10^{19} M^{-2} for double-GATA Zn finger from human), and was able to displace bound Zn from the protein under physiologically relevant conditions (Ghering et al., 2005). Once Pb was bound to GATA proteins, they displayed decreased ability to bind to DNA (Pb concentrations ≥ 1.25 µM) and activate transcription. Pb at a minimum concentration of 10 µM also binds to the Zn domain of TFIIIA, inhibiting its ability to bind DNA at concentrations (Huang et al., 2004; Hanas et al., 1999). Huang et al. (2004) also reported that exposure to Pb caused the dissociation of TFIIIA-DNA adducts and using NMR spectroscopy, found that altered TFIIIA activity was the result of a Pb-induced abnormal protein conformation.

Pb exposure modulated the DNA-binding profiles of the transcription factors Sp1 and Erg-1 in rat pups exposed to 2,000 ppm Pb acetate via lactation, resulting in a shift in DNA-binding toward early development (i.e., the first week following birth) (Reddy and Zawia, 2000; Zawia et al., 1998). The shifts in Sp1 DNA-binding profiles were shown to be associated with abnormal expression of genes related to myelin formation (Section 5.2.7.5). Further mechanistic research utilizing a synthetic peptide containing a Zn finger motif demonstrated that Pb can bind the histidine and cysteine residues of the Zn finger motif, thus displacing Zn and resulting in an increase in the DNA-binding efficiency of the synthetic peptide (Razmiafshari et al., 2001; Razmiafshari and Zawia, 2000). However, in DNA-binding assays utilizing recombinant Sp1 (which has three Zn finger motifs, opposed to only one in the synthetic peptide), 37 µM Pb was the lowest concentration observed to abolish the DNA-binding capabilities of Sp1 (Razmiafshari and Zawia, 2000).

Pb has also been reported to competitively inhibit Mg binding and thus inhibit the activities of adenine and hypoxanthine/guanine phosphoribosyltransferase in erythrocyte lysates from rats exposed to 1,000 ppm Pb in drinking water for 9 months (mean [SD] blood Pb level: 7.01 [1.64] µg/dL) and in in vitro human erythrocyte lysates exposed to 0.1 µM Pb for as little as 5 minutes (Baranowska-Bosiacka et al., 2009), and cGMP phosphodiesterase at 10^{-6} µM concentrations in homogenized bovine retinas (Srivastava et al., 1995). Pb was also reported to inhibit pyrimidine 5'-nucleotidase through competitive inhibition of Mg binding, resulting in conformational changes and improper amino acid positioning in the active site (Bitto et al., 2006).

In summary, Pb has been shown to displace metal cations from the active sites of multiple enzymes and proteins, and thus to alter the functions of those proteins in occupationally-exposed humans with blood Pb levels of 5.4-69.3 µg/dL, in adult rodents with blood Pb levels of 6.5 µg/dL (exposure 4 weeks), in suckling rats exposed to 2,000 ppm Pb via lactation, and in cell-free and cellular in vitro experiments conducted at exposure concentrations ranging from 10^{-6} µM to 1 µM. These alterations in protein function have implications for numerous cellular and physiological processes, including cell signaling, growth and differentiation, gene expression, energy metabolism, and biosynthetic pathways. Table 5-1 provides a list of enzymes and proteins whose function may be perturbed by Pb exposure.

Table 5-1 Enzymes and proteins potentially affected by exposure to Pb and the metal cation cofactors necessary for their proper physiological activity.

	Metalloprotein/Enzyme	Direction of Action[a]	Metal Cation; Reference
Enzymes	Aminolevulinic acid dehydratase	↓	Zn; Simons (1995)
	Ferrochelatase	↓	Fe (2Fe-2S Cluster); Crooks et al. (2010)
	Superoxide dismutase	↓↑	Mn, Cu, Zn, Fe; Antonyuk et al. (2009), Borgstahl et al. (1992)
	Catalase	↓↑	Fe (Heme); Putnam et al. (2000)
	Glutathione peroxidase	↓↑	Se; Rotruck et al. (1973)
	Guanylate cyclase	↓	Fe (Heme); Boerrigter and Burnett (2009)
	cGMP phosphodiesterase	↓	Mg, Zn; Ke (2004)
	NAD synthase	↓	Mg; Hara et al. (2003)
	NAD(P)H oxidase	↑	Ca^{2+}; Leseney et al. (1999)
	Pyrimidine 5'-nucleotidase	↓	Mg, Ca^{2+}; Bitto et al. (2006), Amici et al. (1997), Paglia and Valentine (1975)
	Erythrocyte phosphoribosyltransferase	↓	Mg (Mn, Ca^{2+}, Co, Ni, Zn); Deng et al. (2010), Arnold and Kelley (1978)
Ion Channels/ Transport	ATPase	↓↑	Ca^{2+}, Mg, Na/K; Technische Universitat Braunschweig (2011)

DNA Binding	GATA transcriptional factors	↓	Zn; Hanas et al. (1999), Huang et al. (2004)

[a]↑ indicates increased activity; ↓ indicates decreased activity; ↓↑ indicates activity can be alternatively increased or decreased.

5.2.2.4 Mitochondrial Abnormality

Alterations in mitochondrial function, including disruptions in ion transport, ultrastructural changes, altered energy metabolism, and perturbed enzyme activities due to Pb exposure are well documented in the scientific literature. Exposure of rats to Pb in feed (10,000 ppm Pb for 4, 6, 8, 10, 12, or 20 weeks) or drinking water (300 ppm for 8 weeks, 500 ppm for 7 months, or 10,000 ppm Pb for 9 months) resulted in gross ultrastructural changes in renal tubule mitochondria and epididymal mitochondria characterized as a general swollen appearance with frequent rupture of the outer membrane, distorted cristae, loss of cristae, frequent inner compartment vacuolization, observation of small inclusion bodies, and fusion with adjacent mitochondria (Wang et al., 2010d; Marchlewicz et al., 2009; Navarro-Moreno et al., 2009; Goyer, 1968; Goyer et al., 1968).

Transmembrane mitochondrial ion transport mechanisms have been found to be perturbed by exposure to Pb. Pb inhibits the uptake of Ca^{2+} into mitochondria (Parr and Harris, 1976), while simultaneously stimulating the efflux of Ca^{2+} out of the organelle (Simons, 1993a), thus disrupting intracellular/mitochondrial Ca^{2+} homeostasis. Pb exposure has also been shown to decrease the mitochondrial transmembrane potential in primary cerebellar granule neuronal cultures from rats exposed to 1,000 ppm Pb in drinking water throughout gestation and lactation (Baranowska-Bosiacka et al., 2011b), astroglia incubated with 0.1 or 1.0 µM Pb for 14 days (Legare et al., 1993), proximal tubule cells exposed to 0.25, 0.5, and 1.0 µM for 12 hours (Wang et al., 2009c), and retinal rod photoreceptor cells incubated with 0.01 to 10 µM for 15 minutes (He et al., 2000). Further research indicated that Pb-induced mitochondrial swelling and decreased membrane potential is the result of the opening of a mitochondrial transmembrane pore (MTP), possibly by directly binding to the metal (Ca^{2+})-binding site on the matrix side of the pore (Bragadin et al., 2007; He et al., 2000). Opening of the MTP is the first step of the mitochondrial-regulated apoptotic cascade pathway in many cells (Rana, 2008; Lidsky and Schneider, 2003). He et al. (2000) additionally observed other indicators of apoptosis including, cytochrome c release from mitochondria, and caspase-9 and -3 activation following exposure of retinal rod cells to Pb. Induction of mitochondrially-regulated apoptosis via stimulation of the caspase cascade following exposure to Pb has also been observed in rat hepatic oval cells (Agarwal et al., 2009).

Altered Energy Metabolism

Pb has been reported to alter normal cellular bioenergetics. In mitochondria isolated from the kidneys of rats exposed to 10,000 ppm Pb in feed for 6 weeks, the rate of oxygen uptake during ADP-activated (state 3) respiration was lower compared to controls (Goyer

et al., 1968). The rate of ATP formation from exposed mitochondria was observed to be approximately 50% that of control mitochondria. A decrease in state 3 respiration and respiratory control ratios (state 3/state 4 [succinate or pyruvate/malate-activated]) was also observed in kidney mitochondria from rats exposed continuously from conception to six or nine months of age (i.e., gestationally, lactationally, and via drinking water after weaning) to 50 or 250 ppm Pb (Fowler et al., 1980). Pb-induced decreases in ATP and adenylate energy charge (AEC) were observed concurrently with increases in ADP, AMP, and adenosine in adult rats exposed to 10,000 ppm Pb in drinking water for 9 months (Marchlewicz et al., 2009). Similarly, ATP and AEC were decreased, and AMP increased, in primary cerebellar granule neuronal cultures from rats exposed to 1,000 ppm Pb in drinking water throughout gestation and lactation (Baranowska-Bosiacka et al., 2011b). One µM Pb (48 hours) was the lowest concentration observed to decrease cellular ATP levels in NGF-differentiated PC-12 cells, and these changes were correlated with a Pb-induced decrease in the expression of the mitochondrial voltage-dependent anion channel, which maintains cellular ATP levels in neurons (Prins et al., 2010). Dowd et al. (1990) reported that oxidative phosphorylation was decreased up to 74% after exposure of osteoblasts to 10 µM Pb. Parr and Harris (1976) reported that Pb inhibited both coupled and uncoupled respiratory oxygen use in mitochondria, and that Pb prevented pyruvate, but not malate, uptake. Mitochondrial levels of ATP were diminished after Pb exposure, and the authors compared the effects of Pb on the energy supply to the actions of classic respiratory inhibitors, low temperature, and chemical uncouplers. Bragadin et al. (1998) supported this view by demonstrating that alkylated Pb compounds acted as a chemical uncoupler of respiration by abolishing the proton gradient necessary for oxidative phosphorylation. Further, the enzymatic activities of complex I and IV of the respiratory chain have been shown to be decreased in the peroneous longus muscle of rats exposed to 250 ppm Pb (or 5 ppm thallium) in drinking water for 90 days (Méndez-Armenta et al., 2011). Contrary to the above findings, Rafalowska et al. (1996) reported that, although ATP levels did decrease in the forebrain synaptosomes prepared from rats exposed to 200 ppm Pb in water for 3 months, this chronic exposure to Pb did not inhibit oxidative phosphorylation in the synaptosomal mitochondria. Similar effects with regard to the activity of the mitochondrial oxidative chain were observed in rats injected with 15 mg Pb/kg (i.p.) daily for seven days, as reported by Struzynksa et al. (1997a), although ATP levels were reported to increase after exposure to Pb.

Pb has also been shown to decrease glycolysis in osteoblasts exposed to 10 µM Pb and in human erythrocytes exposed (in vitro) to 30 µg/dL Pb (Grabowska and Guminska, 1996; Dowd et al., 1990). Contrary to these findings, Antonowicz et al. (1990) observed higher levels of glycolytic enzymes in erythrocytes obtained from Pb workers directly exposed to Pb, compared to workers exposed to lower concentrations of Pb (blood Pb levels: 82.1 versus 39.9 µg/dL), and suggested that Pb activated anaerobic glycolysis. In vitro

exposure of human umbilical cord erythrocytes to 100-200 µg/dL Pb for 20 hours was observed to lower the cellular pools of adenine and guanine nucleotide pools, including NAD and NADPH (Baranowska-Bosiacka and Hlynczak, 2003). These decreases in nucleotide pools were accompanied by an increase in purine degradation products (adenosine, etc.). Similar decreases in cellular nucleotide pools were observed when rats were exposed to 10,000 ppm Pb in drinking water for four weeks (Baranowska-Bosiacka and Hlynczak, 2004). In erythrocytes, nucleotides are synthesized via salvage pathways such as the adenine pathway, which requires adenine phosphoribosyltransferase. The activity of this enzyme is inhibited by exposure to Pb in human and rat erythrocytes (see above for concentration and duration) (Baranowska-Bosiacka et al., 2009).

Disruptions in erythrocyte energy metabolism have been observed in adults occupationally exposed to Pb. Nikolova and Kavaldzhieva (1991) reported higher ratios of ATP/ADP in Pb-exposed workers with an average duration of exposure of 8.4 years (blood Pb not reported) than in unexposed controls. Morita et al. (1997) evaluated the effect of Pb on NAD synthetase in the erythrocytes of Pb-exposed workers (mean [SD] blood Pb level: 34.6 [20.7] µg/dL) and observed an apparent concentration-dependent decrease in NAD synthetase activity with increased blood Pb level. The blood Pb level associated with 50% inhibition of NAD synthetase, which requires a Mg^{2+} cation for activity (Hara et al., 2003), was 43 µg/dL.

Altered Heme Synthesis

Exposure to Pb is demonstrated to inhibit two key steps in the synthesis of heme: porphobilinogen synthase (i.e., δ-aminolevulinic acid dehydratase), a cytoplasmic enzyme requiring Zn for enzymatic activity that condenses two molecules of aminolevulinic acid into porphobilinogen, and ferrochelatase, a mitochondrial iron-sulfur containing enzyme that incorporates Fe^{2+} into protoporphyrin IX to create heme. Farant and Wigfield (1990, 1987) observed that Pb inhibits the activity of porphobilinogen synthase in rabbit and human erythrocytes, and that the effect on the enzyme was dependent on the affinity for thiol groups at its active site. Taketani et al. (1985) examined the activity of Pb on ferrochelatase in rat liver mitochondria and observed that 10 µM Pb (30 minute incubation) reduced NAD(P)H-dependent heme synthesis by half when ferric, but not ferrous, iron was used. Pb inhibits the insertion of Fe^{2+} into the protoporphyrin ring and instead, Zn is inserted into the ring creating Zn-protoporphyrin (ZPP). While not directly measuring the activity of ferrochelatase, numerous studies have shown that blood Pb levels are associated with increased erythrocyte ZPP levels in humans (mean blood Pb levels ranging from 21.92 to 53.63 µg/dL) (Mohammad et al., 2008; Counter et al., 2007; Patil et al., 2006b; Ademuyiwa et al., 2005b) and in animals (blood Pb level: 24.7 µg/dL) (Rendón-Ramirez et al., 2007).

In summary, Pb has been shown to disrupt mitochondrial function including transmembrane mitochondrial ion transport mechanisms and has been shown to perturb normal cell bioenergetics. These effects have not only been demonstrated in in vitro toxicological studies but also exposed worker populations.

5.2.3 Protein Binding

Evidence indicates that Pb binds to proteins within cells through interactions with side group moieties (e.g., thiol residues) to form inclusion bodies and can thereby potentially disrupt cellular function (Sections 5.2.2.3 and 5.2.2.4). However, some proteins are also able to bind Pb and protect against its negative effects through sequestration. The ability of Pb to bind proteins was first reported by Blackman (1936). In children exposed to high levels of Pb, formation of intranuclear inclusion bodies in the liver and kidney was observed. Since that time, further research has been conducted into characterizing the composition of intranuclear inclusion bodies and identifying specific Pb-binding proteins.

5.2.3.1 Intranuclear and Cytoplasmic Inclusion Bodies

Goyer (1968) and Goyer et al. (1968) observed the formation of intranuclear inclusion bodies in the renal tubules of rats fed 10,000 ppm Pb in food for up to 20 weeks. The observation of inclusion bodies was accompanied by altered mitochondrial structure and reduced rates of oxidative phosphorylation. Pb has further been observed to form cytoplasmic inclusion bodies preceding the formation of the intranuclear bodies, and to be concentrated within the subsequently induced intranuclear inclusion bodies following i.p. injection, drinking water, and dietary exposures (Navarro-Moreno et al., 2009; Oskarsson and Fowler, 1985; Fowler et al., 1980; McLachlin et al., 1980; Choie and Richter, 1972; Goyer et al., 1970b; Goyer et al., 1970a). Inclusion bodies have also been observed in the mitochondria of kidneys and the perinuclear space in the neurons of rats exposed to 500 ppm Pb acetate in drinking water for 60 days or 7 months (Navarro-Moreno et al., 2009; Deveci, 2006). Intranuclear and cytoplasmic inclusions have also been found in organs other than the kidney, including liver, lung, and glial cells (Singh et al., 1999; Goyer and Rhyne, 1973). Pb found within nuclei has also been shown to bind to the nuclear membrane and histone fractions (Sabbioni and Marafante, 1976).

Upon denaturing intranuclear inclusion bodies with strong denaturing agents, Moore et al. (1973) observed that proteins included in the bodies were rich in aspartic and glutamic acid, glycine, and cysteine. Further work by Moore and Goyer (1974) characterized the protein as a 27.5 kilodalton (kDa) protein that migrates as a single band on

polyacrylamide gel electrophoresis. In contrast with the findings of Moore and Goyer, Shelton and Egle (1982) identified a 32 kDa protein with an isoelectric point of 6.3 from the kidneys of rats exposed to 10,000 ppm Pb acetate in feed or 7,500 ppm in drinking water. This protein, dubbed p32/6.3, was not found in control rats, indicating that the protein was induced by Pb exposure. This finding was in agreement with studies that indicated the formation of intranuclear inclusion bodies required protein synthesis (McLachlin et al., 1980; Choie et al., 1975). In addition to its presence in kidneys of Pb-exposed animals, p32/6.3 has been observed to be present and highly conserved in the brains of rats, mice, dogs, chickens, and humans (Egle and Shelton, 1986). Exposure of neuroblastoma cells to 50 or 100 µM Pb glutamate for 1 or 3 days increased the abundance of p32/6.3 (Klann and Shelton, 1989). Shelton et al. (1990) determined that p32/6.3 was enriched in the basal ganglia, diencephalon, hippocampus, cerebellum, brainstem, spinal cord, and cerebral cortex, and that it contained a high percentage of glycine, aspartic, and glutamic acid residues. Selvin-Testa et al. (1991) and Harry et al. (1996) reported that pre- and post-natal exposure of rats to 2,000–10,000 ppm Pb in drinking water increased the levels of another brain protein, glial fibrillary acidic protein, in developing astrocytes; and that this increase may be indicative of a demand for astrocytes to sequester Pb.

5.2.3.2 Cytosolic Pb Binding Proteins

Numerous studies have also identified cytosolic Pb-binding proteins. Two binding proteins, with molecular weights (MW) of 11.5 and 63 kDa, were identified by Oskarsson et al. (1982) in the kidney postmitochondrial cytosolic fraction prepared from adult male rats after i.p. injection with 50 mg Pb acetate/kg, followed by i.p. injection of 50 µCi ^{203}Pb acetate 6 days later. The two proteins were also found in the brain, but not the liver or lung. Mistry et al. (1985) identified three proteins (MW = 11.5, 63, and >200 kDa) in rat kidney cytosol, two of which, the 11.5 and 63 kDa proteins, were able to translocate into the nucleus. The 11.5 kDa kidney protein was also able to reverse Pb binding to ALAD through chelation of Pb and donation of a Zn cation to ALAD (Goering and Fowler, 1985, 1984). Cd and Zn, but not Ca^{2+} or Fe, prevented the binding of Pb to the 63 and 11.5 kDa cytosolic proteins, which agrees with previous observations that Cd is able to reduce total kidney Pb and prevent the formation of intranuclear inclusion bodies (Mistry et al., 1986; Mahaffey et al., 1981; Mahaffey and Fowler, 1977). Additional cytosolic Pb-binding proteins have been identified in the kidneys of Pb-exposed rats and humans, including the cleavage product of α2-microglobulin, acyl-CoA binding protein (MW = 9 kDa), and thymosin β4 (MW = 5 kDa) (Smith et al., 1998; Fowler and DuVal, 1991).

Cytosolic Pb-binding proteins distinct from kidney proteins have also been identified in the brain of exposed rats, and in human brain homogenates exposed to Pb in vitro (Quintanilla-Vega et al., 1995; DuVal and Fowler, 1989; Goering et al., 1986). One protein (MW = 12 kDa) was shown to alleviate hepatic ALAD inhibition due to Pb exposure through competitive binding with Pb and donation of Zn to ALAD. Cytosolic Pb-binding proteins have been shown to be high in glutamic acid, aspartic acid, and cysteine residues (Fowler et al., 1993; DuVal and Fowler, 1989). Some evidence exists that cytosolic Pb-binding proteins directly target Pb and compartmentalize intracellular Pb as a protective measure against toxicity (Qian et al., 2005; Qian et al., 2000).

5.2.3.3 Erythrocytic Pb Binding Proteins

The majority (94%) of Pb in whole blood is found in erythrocytes (Ong and Lee, 1980a). Originally, the major Pb-binding protein in erythrocytes was identified as hemoglobin (Cohen et al., 2000; Lolin and O'Gorman, 1988; Ong and Lee, 1980a, b; Raghavan and Gonick, 1977). However, Bergdahl et al. (1997b) observed the principal Pb-binding protein to be 240 kDa and identified it as ALAD. Two smaller Pb-binding proteins were observed, but not identified (MW = 45 and <10 kDa). ALAD levels are inducible by Pb exposure; the total concentration of the enzyme, but not the activity, is higher in both Pb-exposed humans (blood Pb = 30-75 µg/dL) and rats (Pb exposure = 2.5×10^{-4} µM in drinking water) (Boudene et al., 1984; Fujita et al., 1982; Fujita et al., 1981).

ALAD is a polymorphic gene with three isoforms: ALAD 1-1, ALAD 1-2, or ALAD 2-2. Carriers of the ALAD-2 allele have been shown to have higher blood Pb levels than carriers of the homozygous ALAD-1 allele (Scinicariello et al., 2007; Zhao et al., 2007; Kim et al., 2004; Pérez-Bravo et al., 2004; Smith et al., 1995a; Wetmur, 1994; Wetmur et al., 1991b; Astrin et al., 1987). Some recent studies, however, either observed lower blood Pb levels in carriers of the ALAD-2 allele or no difference in Pb levels among the different allele carriers (Scinicariello et al., 2010; Krieg et al., 2009; Chen et al., 2008c; Chia et al., 2007; Chia et al., 2006; Wananukul et al., 2006).

The ALAD-2 protein binds Pb more tightly than the ALAD-1form: in Pb-exposed workers carrying the ALAD-2 gene, 84% of blood Pb was bound to ALAD versus 81% in carriers of the ALAD-1 gene ($p = 0.03$) (Bergdahl et al., 1997a). This higher affinity for Pb in ALAD-2 carriers may sequester Pb and prevent its bioavailability for reaction with other enzymes or cellular components. This is supported by the observation that carriers of the ALAD-2 gene have higher levels of hemoglobin (Scinicariello et al., 2007), decreased plasma levulinic acid (Schwartz et al., 1997b), decreased levels of Zn protoporphyrin (Scinicariello et al., 2007; Kim et al., 2004), lower cortical bone Pb

(Smith et al., 1995b), and lower amounts of DMSA-chelatable Pb (Scinicariello et al., 2007; Schwartz et al., 2000a; Schwartz et al., 1997a). However, the findings, that ALAD-2 polymorphisms reduced the bioavailability of Pb, are somewhat equivocal. Wu et al. (2003a) observed that ALAD-2 carriers had lower blood Pb level (5.8 ± 4.2 µg/dL) than carriers of the ALAD-1 gene (blood Pb level = 6.2 ± 4.1 µg/dL), and that ALAD-2 carriers demonstrated decreased renal function at lower patellar Pb concentrations than those associated with decreased renal function in ALAD-1 carriers. This potentially indicates that ALAD-2 carriers have enhanced Pb bioavailability. Weaver et al. (2003b) observed that ALAD-2 polymorphisms were associated with higher DMSA-chelatable Pb concentrations, when normalized to creatinine levels. Further, Montenegro et al. (2006) observed that compared with individuals with the ALAD 1-1 genotype, individuals with the ALAD 1-2/2-2 genotypes had a higher amount of Pb in the plasma (0.44 µg/L versus 0.89 µg/L, respectively) and in the percent plasma/blood ratio (0.48% versus 1.45%, respectively). This potentially suggests that individuals with the ALAD 1-2/2-2 genotype are at increased risk of Pb-induced health effects due to lower amounts of Pb sequestration by erythrocyte ALAD, although this study did not specifically investigate the clinical implications of ALAD polymorphisms.

ALAD has the estimated capacity to bind Pb at 85 µg/dL in erythrocytes and 40 µg/dL in whole blood (Bergdahl et al., 1998). The 45 kDa and <10 kDa Pb-binding proteins bound approximately 12-26% and <1% of the blood Pb, respectively. At blood Pb concentrations greater than 40 µg/dL, greater binding to these components would likely be observed. Bergdahl et al. (1998) tentatively identified the 45 kDa protein as pyrimidine-5'-nucleotidase and the <10 kDa protein as acyl-CoA binding protein. Smith et al. (1998) previously identified acyl-CoA binding protein as a Pb-binding protein found in the kidney.

5.2.3.4 Metallothionein

In adults occupationally exposed to Pb, the presence of an inducible, low-molecular weight (approximately 10 kDa) Pb-binding protein was identified in multiple early studies (Gonick et al., 1985; Raghavan et al., 1981, 1980; Raghavan and Gonick, 1977). The presence of this low molecular weight protein seemed to have a protective effect, as workers who exhibited toxicity at low blood Pb concentrations were observed to have lowered expression of this protein or low levels of Pb bound to it (Raghavan et al., 1981, 1980). The presence of low molecular weight Pb-binding proteins in exposed workers was corroborated by Lolin and O'Gorman (1988) and Church et al. (1993a, b). Further Lolin and O'Gorman (1988) reported that the observed protein was only present when blood Pb levels were greater than 39 µg/dL, in agreement with the Pb-binding capacity of

ALAD, identified by Bergdahl et al. (1998). Xie et al. (1998) confirmed this, observing the presence of a second low molecular weight protein with greater affinity than ALAD, only at higher blood Pb levels. Church et al. (1993a, b) observed the presence of a 6-7 kDa protein in the blood of two Pb workers (blood Pb >160 µg/dL); approximately 67% of Pb was bound to the protein in the blood of the asymptomatic worker, whereas only 22% of the Pb was bound to it in the symptomatic (tremor, ataxia, extremity numbness) worker. The reported protein was rich in cysteine residues and tentatively identified as metallothionein.

Metallothionein is a low-MW metal-binding protein, most often binding Zn or Cu, that is rich in cysteine residues and plays an important role in protecting against heavy metal toxicity, maintaining trace element homeostasis, and scavenging free radicals (Yu et al., 2009). Exposure to Pb acetate induced the production of Pb- and Zn-metallothionein in mice treated via i.p. or intravenous (i.v.) injection at 30 mg/kg (Maitani et al., 1986), in mice treated via i.p. injection at 300 µmol/kg (Yu et al., 2009), or in rats treated via i.p. injection at 24 µmol/100g (Ikebuchi et al., 1986). The induced Pb-metallothionein consisted of 28% half-cysteine and reacted with an antibody for Zn-metallothionein II (Ikebuchi et al., 1986). In contrast, exposure of rats to Pb via drinking water (200 or 300 ppm) failed to induce metallothionein in the kidneys or intestines (Wang et al., 2009b; Jamieson et al., 2007). Goering and Fowler (1987a, b) observed that pretreatment of rats with Zn before injection with Pb resulted in Pb and Zn co-eluting with Zn-thionein, and that Zn-thionein I and II were able to bind Pb in vitro (Goering and Fowler, 1987a, b). Further, Goering and Fowler (1987a) found that kidney and liver Zn-thionein decreased binding of Pb to liver ALAD and was able to donate Zn to ALAD, thus attenuating the inhibition of ALAD due to Pb exposure. These findings are in agreement with Goering et al. (1986) and DuVal and Fowler (1989) who demonstrated that rat brain Pb-binding proteins attenuated Pb-induced inhibition of ALAD.

Metallothionein has been reported to be important in the amelioration of Pb-induced toxicity effects. Liu et al. (1991) reported that Zn-metallothionein reduced Pb-induced membrane leakage and loss of K^+ in cultured hepatocytes incubated with 600-3,600 µM Pb. Metallothionein-null mice exposed to 1,000, 2,000, or 4,000 ppm Pb for 20 weeks suffered renal toxicity described as nephromegaly and decreased renal function compared to Pb-treated wild-type mice (Qu et al., 2002). Interestingly, metallothionein-null mice were unable to form intranuclear inclusion bodies and accumulated less renal Pb than did the wild-type mice (Qu et al., 2002). Increased metallothionein levels were induced by Pb exposure in non-null mice. Exposure to Pb (1,000, 2,000, or 4,000 ppm), both for 104 weeks as adults and from GD8 to early adulthood, resulted in increased preneoplastic lesions and carcinogenicity in the testes, bladder, and kidneys of metallothionein-null rats compared to wild type mice (Tokar et al., 2010; Waalkes et al., 2004). Inclusion bodies

were not observed in null mice. The authors concluded that metallothionein is important in the formation of inclusion bodies and in the mitigation of Pb-induced toxic effects, and that those with polymorphisms in metallothionein coding genes that are associated with reduced inducibility may be at greater susceptibility to Pb. In support of this theory, Chen et al. (2010a) observed that Pb-exposed workers with a mutant metallothionein allele had higher blood Pb levels than did carriers of the normal allele (24.17 and 21.27 versus 17.03 µg/dL), and had larger blood Pb-associated changes in systolic BP and serum renal function parameters.

In summary, a number of proteins have been identified that can bind and sequester Pb including ALAD and metallothionein. Additionally, evidence suggests that certain polymorphisms that alter the binding capability or inducibility of these proteins can increase the risk of Pb induced health effects.

5.2.4 Oxidative Stress

Oxidative stress occurs when free radicals or reactive oxygen species (ROS) exceed the capacity of antioxidant defense mechanisms. This oxidative imbalance results in uncontained ROS, such as superoxide (O_2^-), hydroxyl radical (OH), and hydrogen peroxide (H_2O_2), which can attack and denature functional/structural molecules and, thereby, promote tissue damage, cytotoxicity, and dysfunction. Pb exposure has been shown to cause oxidative damage to the heart, liver, kidney, reproductive organs, brain, and erythrocytes, which may be responsible for a number of Pb-induced health effects (Salawu et al., 2009; Shan et al., 2009; Vaziri, 2008b; Gonick et al., 1997; Sandhir and Gill, 1995; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1992a). The origin of ROS (produced after Pb exposure) is likely a multipathway process, resulting from oxidation of δ-aminolevulinic acid (ALA), membrane and lipid oxidation, NAD(P)H oxidase activation, and antioxidant enzyme depletion, as discussed below. Some of these processes result from the disruption of functional metal ions within oxidative stress enzymes, such as superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx). Interestingly, Pb exposure in many species of plants, invertebrates, and vertebrates discussed in Chapter 7 (*Ecological Effects of Lead*) results in upregulation of antioxidant enzymes and increased lipid peroxidation. Oxidative stress is a common mode of action for a number of other metals (e.g., Cd, Mn, As, Co, Cr) that are often found with Pb and by which possible interactions with Pb have been suggested to occur (Jomova and Valko, 2011; Jomova et al., 2011; Matović et al., 2011; HaMai and Bondy, 2004). Not all of these co-occurring metals directly produce ROS or redox cycle, but instead may suppress the free radical scavenging ability of the organism thus leading to oxidative stress.

5.2.4.1 δ-ALA Oxidation

The majority of Pb present in the blood accumulates in erythrocytes where it enters through passive carrier-mediated mechanisms including a vanadate-sensitive Ca^{2+} pump. Once Pb enters erythrocytes, it is predominantly found in the protein-bound form, with hemoglobin and δ-ALAD both identified as targets (Bergdahl et al., 1997a). Through its sulfhydryl and metal ion disrupting properties, Pb incorporates with and inhibits a number of enzymes in the heme biosynthetic process, including δ-ALA synthetase, δ-ALAD, and ferrochelatase. Pb has been shown to be able to disrupt the Zn ions requisite for the activity of δ-ALAD, the rate limiting step in heme synthesis, leading to enzyme inhibition at 10^{-6} µM concentrations (Simons, 1995). Additionally, blood Pb levels (mean: 7 µg/dL) have been associated with inhibited activity of δ-ALAD in humans, and the lowest blood Pb level observed to be associated with lower δ-ALAD activity in these studies was 5 µg/dL (Ahamed et al., 2005; Sakai and Morita, 1996). A negative correlation (r = -0.6) was found between blood Pb levels in adolescents (range of blood Pb levels: 4 to 20 µg/dL) and blood δ-ALAD activity (Ahamed et al., 2006). This inhibition of δ-ALAD results in the accumulation of δ-ALA in blood and urine, where δ-ALA undergoes tautomerization and autoxidation. Oxidized δ-ALA generates ROS through reduction of ferricytochrome *c* and electron transfer from oxyHb, metHb, and other ferric and ferrous iron complexes (Hermes-Lima et al., 1991; Monteiro et al., 1991). The autoxidation of δ-ALA produces O_2^-, OH , H_2O_2, and an ALA radical (Monteiro et al., 1989; Monteiro et al., 1986).

5.2.4.2 Membrane and Lipid Peroxidation

A large number of studies in humans and experimental animals have indicated that exposure to Pb can lead to membrane and lipid peroxidation. It is possible that ROS produced from δ-ALA oxidation, as described above, interacts with and disrupts membrane lipids (Oteiza et al., 1995; Bechara et al., 1993). Additionally, Pb has the capacity to stimulate ferrous ion initiated membrane lipid peroxidation serving as a catalyst for these events (Adonaylo and Oteiza, 1999; Quinlan et al., 1988). The extent of peroxidation of lipids varies based on the number of double bonds present in unsaturated fatty acids, since double bonds weaken the C-H bonds on the adjacent carbon, making hydrogen (H) removal easier (Yiin and Lin, 1995). After the essential unsaturated fatty acid solutions were incubated with Pb (4-12 µg/dL, 24 hours), the production of malondialdehyde (MDA), a marker of oxidative stress and lipid oxidation end product, increased relative to the number of double bonds of the fatty acid (Yiin and Lin, 1995). In the absence of Fe^{2+}, Pb has not been shown to promote lipid peroxidation; however, it may accelerate peroxidation by H_2O_2 (Quinlan et al., 1988). This could be due to altering

membrane structure, restricting phospholipid movement, and facilitating the propagation of peroxidation.

Pb induces changes in the fatty acid composition of a membrane, which could lead to oxidative damage. Exposure to Pb (>62.5 ppm in drinking water, 3 weeks) in chicks promoted an increase in arachidonic acid (20:4) as a percentage of total fatty acids, and decreased the relative proportion of shorter chain fatty acids (linoleic acid, 18:2) (Lawton and Donaldson, 1991). It is possible that Pb depressed the desaturation of saturated fatty acids to the corresponding monoenoic fatty acids, while stimulating elongation and desaturation of linoleic acid to arachidonic acid. Since fatty acid chain length and unsaturation are related to the oxidative potential, changes in fatty acid membrane composition may result in enhanced lipid peroxidation. In addition, changes in fatty acids, thus membrane composition, can result in altered membrane fluidity (Donaldson and Knowles, 1993). Changes in membrane fluidity will disturb the conformation of the active sites of membrane associated enzymes, disrupt metabolic regulation, and alter membrane permeability and function.

A number of recent studies report increased measures of lipid peroxidation in various organs, tissues, and species in association with Pb. Occupational Pb exposure resulting in elevated blood Pb levels (means >8 µg/dL) reported in various countries provides evidence of lipid peroxidation, including increased plasma MDA levels (Ergurhan-Ilhan et al., 2008; Khan et al., 2008; Mohammad et al., 2008; Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b). One study found a correlation between the MDA levels and blood Pb levels even in the unexposed workers, although they had blood Pb levels higher than the mean blood Pb level of the current U.S. population (i.e., <12 µg/dL) (Quintanar-Escorza et al., 2007). Other studies found evidence of increased lipid peroxidation among the general population, including children, with elevated blood Pb levels (means >10 µg/dL) (Ahamed et al., 2008; Ahamed et al., 2006; Jin et al., 2006). In adolescents, Ahamed et al. (2006) found a blood MDA levels to be positively correlated (r = 0.7) with concurrent blood Pb levels ranging between 4 and 20 µg/dL. Similar results have been shown after Pb exposure in animal studies (Abdel Moneim et al., 2011b; Pandya et al., 2010; Dogru et al., 2008; Yu et al., 2008; Adegbesan and Adenuga, 2007; Lee et al., 2005). Enhanced lipid peroxidation has been found in Pb treated (50 µg, 1-4 hours) rat brain homogenates (Rehman et al., 1995), rat proximal tubule cells (0.5-1 µM, 12 hours) (Wang et al., 2011b), and in specific brain regions, hippocampus and cerebellum, after Pb exposure (500 ppm, 8 weeks) to rats (Bennet et al., 2007). Overall, there was a correlation between the blood Pb level and measures of lipid peroxidation often measured by MDA levels.

In summary, studies in humans and animals provide evidence for increased lipid and membrane oxidation following Pb exposure. Interestingly, many species of plants, invertebrates, and other vertebrates also exhibit increased lipid peroxidation with Pb exposure (Sections 7.3.12.6 and 7.4.12.6). The increase in lipid peroxidation following Pb exposure observed across species and kingdoms demonstrate an evolutionarily conserved oxidative response following Pb exposure.

5.2.4.3 NAD(P)H Oxidase Activation

NAD(P)H oxidase is a membrane bound enzyme that requires Ca^{2+} in order to catalyze the production of O_2^- from NAD(P)H and molecular oxygen (Leseney et al., 1999). Two studies provide evidence for increased activation of NAD(P)H oxidase that may contribute to the production of ROS after Pb exposure (Ni et al., 2004; Vaziri et al., 2003). Vaziri et al. (2003) found increased protein expression of the NAD(P)H subunit gp^{91}phox in the brain, heart, and renal cortex of Pb-treated rats (100 ppm in drinking water, 12 weeks). This upregulation was present in Pb-treated (1-10 ppm) human coronary artery endothelial cells, but not vascular smooth muscle cells (VSMC), which do not express the protein (Ni et al., 2004). It is possible that NAD(P)H oxidase serves as a potential source of ROS in cells that express this protein.

5.2.4.4 Antioxidant Enzyme Disruption

Oxidative stress can result not only from the increased production of ROS, but also from the decreased activity of antioxidant defense enzymes. Pb has been shown to alter the function of several antioxidant enzymes, including SOD, CAT, glucose-6-phosphate dehydrogenase (G6PD), and the enzymes involved in glutathione metabolism, GPx, glutathione-S-transferase (GST), and glutathione reductase (GR). These changes in the antioxidant defense system could be due to the high affinity of Pb for sulfhydryl groups contained within proteins and its metal ion mimicry. However changes could also be a consequence of increased oxidative damage by Pb.

Studies of the effects of Pb exposure on the activities of SOD and CAT give divergent results. These metalloprotein enzymes require various essential trace elements for proper structure and function, making them a target for Pb toxicity. CAT is a heme containing protein that requires Fe ions to function (Putnam et al., 2000). SOD exists in multiple isoforms that require Cu and Zn (SOD1 and SOD3) (Antonyuk et al., 2009) or Mn (SOD2) (Borgstahl et al., 1992). A number of studies have found decreased activity of these enzymes (Pandya et al., 2010; Ergurhan-Ilhan et al., 2008; Mohammad et al., 2008;

Yu et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Conterato et al., In Press), whereas others have observed increased activity following Pb exposure (Ahamed et al., 2008; Lee et al., 2005). The heterogeneity in species examined, (i.e., humans, rodents, boars), and Pb exposure metrics reported did not permit evaluation of whether a nonlinear concentration-response relationship could explain heterogeneity in findings. Pb exposure (500 ppm Pb acetate, 1, 4, and 8 weeks) in adult male rats showed that SOD and CAT activity responded differently depending on the brain region analyzed and length of exposure (Bennet et al., 2007). Another study found that the brain had consistently decreased SOD activity, irrespective of dose in prenatally-exposed animals (0.3 and 3.0 ppm, blood Pb level 20.4 and 24.5 µg/dL); however hepatic SOD activity increased at low level Pb administration and decreased after high level exposure (Uzbekov et al., 2007). It is possible that the increased activity of the SOD and CAT proteins is due to activation by ROS, while decreased enzyme activity is the result of metal ion substitution by Pb, causing enzyme inactivation.

Glutathione is a tripeptide antioxidant containing a cysteine with a reactive thiol group that can act nonenzymatically as a direct antioxidant or as a cofactor in enzymatic detoxification reactions by GST. Glutathione will donate an electron while in its reduced state (GSH), which leads to conversion to the oxidized form, glutathione disulfide (GSSG). Pb binds to the thiol and can both interfere with the antioxidant capacity of GSH, and can decrease levels of GSH. Short-term administration of Pb in vitro (0.1 µM) and observed biomarkers of Pb exposure in humans (18 µg/dL mean blood Pb level) have been associated with decreased blood and organ GSH and cysteine content, which may be due to increased GSH efflux from tissues (Pandya et al., 2010; Pillai et al., 2010; Ahamed et al., 2009; Ahamed et al., 2008; Flora et al., 2007; Ahamed et al., 2005; Chetty et al., 2005; Nakagawa, 1991, 1989). Long-term Pb exposure has elicited a compensatory upregulation in the biosynthesis of GSH in the attempt to overcome Pb toxicity, thus often manifesting as an increase in Pb-induced GSH in animals (Daggett et al., 1998; Corongiu and Milia, 1982; Hsu, 1981) and occupationally exposed adults (SRC, 2002; Conterato et al., In Press). However, other studies have found that long-term Pb exposure, resulting in mean blood Pb levels between 6.6 and 22 µg/dL, causes the depletion of GSH in animals (Lee et al., 2005; Ercal et al., 1996) and occupationally exposed adults (Mohammad et al., 2008). Thus, the duration of Pb exposure is important to consider when measuring GSH levels.

Glutathione reductase is able to reduce GSSG back to GSH. Therefore, an increased GSSG/GSH ratio is considered to be indicative of oxidative stress. Epidemiologic studies have found higher blood Pb levels to be associated with increases in the GSSG/GSH ratio (Mohammad et al., 2008; Ercal et al., 1996; Sandhir and Gill, 1995). In one study, this association was observed in a population of children with a mean blood Pb level below

10 µg/dL (Diouf et al., 2006). Studies have found mixed effects on GR activation. GR possesses a disulfide at its active site that is a target for inhibition by Pb. Studies in animals and cells have reported decreased (Bokara et al., 2009; Sandhir and Gill, 1995; Sandhir et al., 1994), increased (Sobekova et al., 2009; Howard, 1974), and no change (Hsu, 1981) in GR activity after Pb exposure. This could be because the effect of Pb on GR varies depending on sex (Sobekova et al., 2009), and organ or organ region (Bokara et al., 2009). The heterogeneity in species examined, (i.e., humans, rodents), and Pb exposure duration and metrics reported did not permit evaluation of whether a nonlinear concentration-response relationship could explain heterogeneity in findings.

GSH is used as a cofactor for peroxide reduction and detoxification of xenobiotics by the enzymes GPx and GST. GPx requires Se (selenium) for peroxide decomposition (Rotruck et al., 1973), whereas GST functions via a sulfhydryl group. Evidence indicates that by reducing the uptake of Se, depleting cellular GSH, and disrupting protein thiols, Pb decreases the activity of GPx and GST (Pillai et al., 2010; Yu et al., 2008; Lee et al., 2005; Nakagawa, 1991; Schrauzer, 1987). Similar to other antioxidant enzymes, compensatory upregulation of these enzymes was observed after Pb exposure in animals and in Pb-exposed workers (painters with a mean blood Pb level of 5.4 µg/dL) (Bokara et al., 2009; Ergurhan-Ilhan et al., 2008; Conterato et al., 2007; Daggett et al., 1998; Conterato et al., In Press). However, in another study, these enzymes were not able to compensate for the increased Pb-induced ROS, further contributing to the oxidative environment (Farmand et al., 2005).

Recently, γ-glutamyltransferase (GGT) within its normal range has been regarded as an early and sensitive marker of oxidative stress. This may be because cellular GGT metabolizes extracellular GSH to be used in intracellular GSH synthesis. Thus, cellular GGT acts as an antioxidant enzyme by increasing the intracellular GSH pool. However, the reasons for the association between GGT and oxidative stress have not been fully realized (Lee et al., 2004). In one study, occupational Pb exposure (mean blood Pb level of 29.1 µg/dL) was associated with increased serum GGT levels (Khan et al., 2008). Interestingly, higher blood Pb level was similarly associated with higher serum GGT levels in a sample of the U.S. adult population (NHANES III) (Lee et al., 2006a). In this study of nonoccupationally-exposed individuals, a concentration-dependent relationship was observed with blood Pb levels <7 µg/dL.

In summary, Pb has been shown to alter the function of several antioxidant enzymes, including SOD, CAT, G6PD, and the enzymes involved in glutathione metabolism, GPx, GST, and GR in human populations and experimental animal models. Alteration of these enzymes may lead to further oxidative stress following Pb exposure.

5.2.4.5 Nitric Oxide Signaling

NO (nitric oxide radical), also known as endothelium-derived relaxing factor, is a potent endogenous signaling molecule involved in vasodilation. Short- and long-term Pb exposure in animals have been found to decrease the biologically active NO, not through reduction in NO-production capacity (Vaziri and Ding, 2001; Vaziri et al., 1999a), but as a result of inactivation and sequestration of NO by ROS (Malvezzi et al., 2001; Vaziri et al., 1999b). Endogenous NO can interact with ROS, specifically O_2^-, produced following exposure to Pb to form the highly cytotoxic reactive nitrogen species, peroxynitrite ($ONOO^-$). This reactive compound can damage cellular DNA and proteins, resulting in the formation of nitrotyrosine among other products. Overabundance of nitrotyrosine in plasma and tissues is present after exposure to Pb (Vaziri et al., 1999b). NO is also produced by macrophages in the defense against certain infectious agents, including bacteria. Studies have indicated that Pb exposure can significantly reduce production of NO in human (Pineda-Zavaleta et al., 2004) and animal immune cells (Lee et al., 2001b; Tian and Lawrence, 1995), possibly leading to reduced host resistance (Tian and Lawrence, 1996).

Production of NO is catalyzed by a family of enzymes called nitric oxide synthases (NOS), including endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS), which require a heme prosthetic group and a Zn cation for enzymatic activity (Messerschmidt et al., 2001). Paradoxically, the reduction in NO availability in vascular tissue following Pb exposure is accompanied by statistically significant upregulation in NOS isotypes (Vaziri and Ding, 2001; Vaziri et al., 1999a; Gonick et al., 1997). A direct inhibitory action of Pb on NOS enzymatic activity has been rejected (Vaziri et al., 1999a). Instead, the upregulation of NOS occurs as compensation for the decreased NO resulting from ROS inactivation (Vaziri et al., 2005; Vaziri and Ding, 2001; Vaziri and Wang, 1999).

Soluble Guanylate Synthase

Many biological actions of NO, such as vasorelaxation, are mediated by cyclic guanosine monophosphate (cGMP), which is produced by soluble guanylate cyclase (sGC) from the substrate guanosine triphosphate. Soluble guanylate cyclase is a heterodimer requiring one molecule of heme for enzymatic activity (Boerrigter and Burnett, 2009). In VSMC, sGC serves as the NO receptor. Marked reduction in plasma concentrations and urinary excretion of cGMP is observed after Pb exposure to rats [5 ppm Pb in drinking water for 30 days (Marques et al., 2001)] and [100 ppm Pb acetate in drinking water for 3 months, resulting in a mean blood Pb level of 29.4 µg/dL) (Khalil et al., 2008)] (Marques et al., 2001; Khalil-Manesh et al., 1993b). In addition, Pb exposure downregulated the protein

abundance of sGC in vascular tissue (Farmand et al., 2005; Courtois et al., 2003; Marques et al., 2001). This downregulation in sGC was prevented by antioxidant therapy (ascorbic acid) suggesting that oxidative stress also plays a role in Pb-induced downregulation of sGC (no change in blood Pb level was observed after ascorbic acid treatment) (Marques et al., 2001).

5.2.5 Inflammation

Misregulated inflammation represents one of the major hallmarks of Pb-induced immune effects. It is important to note that this can manifest in any tissue where immune cell mobilization and tissue insult occurs. Enhanced inflammation and tissue damage occurs through the modulation of inflammatory cell function and production of pro-inflammatory cytokines and metabolites. Overproduction of ROS and an apparent depletion of antioxidant protective enzymes and factors (e.g., Se) accompany this immunomodulation (Chetty et al., 2005).

Traditional immune-mediated inflammation can be seen with bronchial hyperresponsiveness, asthma, and respiratory infections, some of which have been associated with exposure to Pb. But it is important to recognize that any tissue or organ can be affected by immune-mediated inflammatory dysfunction given the distribution of immune cells as both permanent residents and infiltrating cell populations (Mudipalli, 2007; Carmignani et al., 2000). Pb has been associated with multiple indicators of inflammation in multiple cell types. Pb has also induced renal tubulointerstitial inflammation (100 ppm exposure for 14 weeks) (Rodriguez-Iturbe et al., 2005) (24.6 µg/dL blood Pb level, 150 ppm for 16 weeks) (Roncal et al., 2007). Renal tubulointerstitial inflammation has been coupled with activation of the redox sensitive nuclear transcription factor kappa B (NFκB) and lymphocyte and macrophage infiltration in rats (100 ppm for 14 weeks resulting in mean blood Pb levels ranging 23.7 µg/dL) (Bravo et al., 2007). These events could be in response to the oxidative environment arising from Pb exposure, since Pb-induced inflammation and NFκB activation can be ameliorated by antioxidant therapy (Rodriguez-Iturbe et al., 2004). Pb spheres implanted in the brains of rats produced neutrophil-driven inflammation with apoptosis and indications of neurodegeneration (Nakao et al., 2010).

Inflammation can be mediated by the production of chemical messengers such as prostaglandins (PG). Pb exposure has been associated with increased arachidonic acid (AA) metabolism, thus elevating the production of PGE_2, PGF_2, and thromboxane in occupationally-exposed humans (mean blood Pb level 48 µg/dL) (Cardenas et al., 1993) and animal and cell models (e.g., 0.01 µM, 48 hours) (Chetty et al., 2005; Flohé et al.,

2002; Knowles and Donaldson, 1997; Lee and Battles, 1994). Dietary Pb exposure of animals (500 ppm, 19 days) can increase the percentage of cell membrane AA, the precursor of cyclooxygenase and lipoxygenase metabolism to PGs and leukotrienes (Knowles and Donaldson, 1990). Additionally, Pb (1 µM) may promote the release of AA via activation of phospholipase A_2, as shown in isolated VSMC (Dorman and Freeman, 2002).

Inflammation may be the result of increased pro-inflammatory signaling or may stimulate these signaling pathways. Pb can elevate the expression of the pro-inflammatory transcription factors NFκB and activator protein-1 (AP-1), as well as the AP-1 component c-Jun (Korashy and El-Kadi, 2008; Korashy and Ei-Kadi, 2008; Bravo et al., 2007; Ramesh et al., 1999; Pyatt et al., 1996). Pb exposure (25 µM) to dendritic cells stimulated phosphorylation of the Erk/MAPK pathway, but not p38, STAT3 or 5, or CREB (Gao et al., 2007)

5.2.5.1 Cytokine Production

There are three modes by which Pb has been shown to affect immune cytokine production. First, Pb can act on macrophages to elevate the production of pro-inflammatory cytokines such as TNF-α and interleukin (IL)-6 (Cheng et al., 2006; Chen et al., 1999; Dentener et al., 1989). This can result in local tissue damage during the course of immune responses affecting such targets as the liver. Second, Pb can skew the ratio of IL-12/IL-10 such that T-derived lymphocyte helper (Th)1 responses are suppressed and Th2 responses are promoted (Chen et al., 2004; Miller et al., 1998) possibly by affecting dendritic cells. Third, when acquired immune responses occur following exposure to Pb, Th1 lymphocyte production of cytokines is suppressed (e.g., IFN-γ) (Lynes et al., 2006; Heo et al., 1996); in contrast, Th2 cytokines such as IL-4, IL-5, and IL-6 are elevated (Gao et al., 2007; Kim and Lawrence, 2000). The combination of these three modes of cytokine changes induced by Pb can create a hyperinflammatory state among innate immune cells and skew acquired immunity toward Th2 responses.

Iavicoli et al. (2006b) reported that low blood Pb concentrations produced significant changes in cytokine levels in mice. At a low dietary Pb concentration (0.11 ppm, blood Pb level of 1.6 µg/dL), IL-2 and IFN-γ were decreased compared to the controls (0.02 ppm, 0.8 µg/dL), indicating a suppressed Th1 response. As the dietary and blood Pb concentrations increased (resulting in blood Pb levels 12-61 µg/dL), a Th2 phenotype was observed with suppressed IFN-γ and IL-2 and elevated IL-4 production. These findings support the notion that the immune system is remarkably sensitive to Pb-induced

functional alterations and that nonlinear effects may occur at low Pb exposures. TGF-β production was also altered by Pb exposure to transfected mouse limb bud mesenchymal stem cells (1 µM, 3 days) (Zuscik et al., 2007). IL-2 is one of the more variable cytokines with respect to Pb-induced changes. Depending upon the protocol it can be slightly elevated in production or unchanged. Recently, Gao et al. (2007) found that Pb-treated dendritic cells (25 µM) promoted a slight but statistically significant increase in IL-2 production among lymphocytes. Proinflammatory cytokines have been measured in other organs and cell types after Pb exposure. Elevation of IL-1β and TNF-α were observed in the hippocampus after Pb treatment (15 ppm, i.p., daily for 2 weeks, blood Pb level of 30.8 µg/dL) and increased IL-6 was found in the forebrain (Strużyńska et al., 2007).

Consistent with animal studies, epidemiologic studies also found higher concurrent blood Pb levels in children and occupationally-exposed adults to be associated with a shift toward production of Th2 cytokines relative to Th1 cytokines. The evidence in children was based on comparisons of serum cytokine levels among groups with different blood Pb levels without consideration of potential confounding factors. Among children ages 9 months to 6 years in Missouri, Lutz et al. (1999) found that children with concurrent blood Pb levels 15-19 µg/dL had higher serum levels of IL-4 and IgE (Section 5.6.3) than did children with lower blood Pb levels. These results were consistent with the mode of action for IL-4 to activate B cells to induce B cell class switching to IgE. Concurrent blood Pb levels did not differ by residence in old versus new homes or by urban versus rural residence (means: 3.2-3.8 µg/dL) but were higher among children living near an oil refinery, in particular, among children with known respiratory allergies (mean: 8.8 µg/dL). This latter group of children also had the lowest serum levels of IFN-γ and highest levels of IL-4. There was no direct comparison of cytokine levels between blood Pb level groups in the population overall; however, cytokine levels were similar between healthy and allergy groups in the other Pb source groups that had similar blood Pb levels. Thus, the differences in cytokine levels between healthy and allergic children living near the oil refinery may have been influenced by differences in their blood Pb levels or other factors related to residence near an oil refinery.

Evidence of association between blood Pb levels and cytokine levels in nonoccupationally-exposed adults was unclear. Among healthy adult university students in Incheon, Korea, Kim et al. (2007) found associations of concurrent blood Pb level with serum levels of TNF-α and IL-6 that were larger among male students with blood Pb levels 2.51-10.47 µg/dL. Notably, the relative contributions of lower recent versus higher past Pb exposures to these cytokine effects is not known. In models that adjusted for age, sex, BMI, and smoking status, a 1 µg/dL increase in blood Pb level was associated with a 23% increase (95% CI: 4, 55%) in log of TNF-α and a 26% increase in log of IL-6 (95% CI: 0, 55%). The association between levels of blood Pb and plasma TNF-α was greater

among men who were GSTM1 null or had the TNF-α GG genotype. For the association between blood Pb level and plasma IL-6, the effect estimate was slightly elevated in TNF-α GG genotype but not elevated in the GSTM1 positive group. The effects of Pb on several physiological systems have been hypothesized to be mediated by the generation of ROS (Daggett et al., 1998). Thus, the null variant of GSTM1, which is associated with reduced elimination of ROS, may increase the risk of Pb-associated immune effects. The results for the TNF-α polymorphism are difficult to interpret. The GG genotype is associated with lower expression of TNF-α, and the literature is mixed with respect to which variant increases risk of inflammation-related conditions. A study of adults in Italy did not provide quantitative results and only reported a lack of statistically significant correlation between blood Pb levels with Th2 or Th1 cytokine levels in men (Boscolo et al., 1999) and women (Boscolo et al., 2000).

Results from studies of occupationally-exposed adults also suggested that Pb exposure may be associated with decreases in Th1 cytokines and increases in Th2 cytokines; however, analyses were mostly limited to comparisons of levels among different occupational groups with different mean blood Pb levels (Di Lorenzo et al., 2007; Valentino et al., 2007; Yücesoy et al., 1997a) without consideration for potential confounding factors including other occupational exposures. An exception was a study of male foundry workers, pottery workers, and unexposed workers by Valentino et al. (2007). Although quantitative regression results were not provided, higher blood Pb level was associated with higher IL-10 and TNF-α with adjustment for age, BMI, smoking, and alcohol consumption. In analyses of blood Pb groups, levels of IL-2, IL-10, and IL-6 also increased from the lowest to highest blood Pb group. In contrast with most other studies, both exposed worker groups had lower IL-4 levels compared with controls. In a similar analysis, DiLorenzo et al. (2007) separated exposed workers into intermediate (9.1-29.4 µg/dL) and high (29.4-81.1 µg/dL) blood Pb level groups, with unexposed workers comprising the low exposure group (blood Pb levels 1-11 µg/dL). Mean TNF-α levels showed a monotonic increase from the low to high blood Pb group. Levels of granulocyte colony-stimulating factor (G-CSF) did not differ between the intermediate and high blood Pb groups among the Pb recyclers; however, G-CSF levels were higher in the Pb recyclers than in the unexposed controls. Furthermore, among all subjects, blood Pb showed a strong, positive correlation with G-CSF. Yucesoy et al. (1997a) found lower serum levels of the Th1 cytokines, IL-1β and IFN-γ, in workers (mean blood Pb level of 59.4 µg/dL) compared with controls (mean blood Pb level of 4.8 µg/dL); however levels of the Th2 cytokines, IL-2 and TNF-α levels, were similar between groups. As most occupationally-exposed cohorts represent populations highly exposed to Pb (with mean blood Pb levels >22 µg/dL), effects observed within these cohorts may not be generalizable to the population as a whole.

In summary, animal, general population, and occupational studies suggest that exposure to Pb increases the production of pro-inflammatory cytokines, skews the ratio of Th1 and Th2 cytokines to favor Th2 responses, and suppresses lymphocyte cytokine production.

5.2.6 Endocrine Disruption

5.2.6.1 Hypothalamic-Pituitary-Gonadal Axis

Evidence indicates that Pb is a potent endocrine disrupting chemical found to be associated with reproductive and developmental effects in both male and female animal models (see Section 5.8). Pb may act both at multiple points along the hypothalamic-pituitary-gonadal (HPG) axis and directly at gonadal sites. The HPG axis functions in a closely regulated manner to produce circulating sex steroids and growth factors required for normal growth and development. Long-term Pb exposure in animals has been shown to alter serum levels of follicle-stimulating hormone (FSH), luteinizing hormone (LH), testosterone, and estradiol (Biswas and Ghosh, 2006; Rubio et al., 2006). Similar changes in serum HPG hormones have been observed after high-level Pb exposure in animals, resulting in blood Pb levels >20 µg/dL (Dearth et al., 2002; Ronis et al., 1998b; Foster, 1992; Sokol and Berman, 1991). Increases in serum LH and FSH have been associated with increasing concurrent blood Pb levels in adult women from the NHANES cohort (Krieg, 2007). The change in HPG hormones likely occurs through the inhibition of LH secretion and the reduction in the expression of the steroidogenic acute regulatory protein (StAR) (Huang and Liu, 2004; Srivastava et al., 2004; Huang et al., 2002; Ronis et al., 1996). StAR expression is the rate-limiting step essential in maintaining gonadotropin-stimulated steroidogenesis, which results in the formation of testosterone and estradiol. Prenatal and lactational Pb exposure (resulting in 3 µg/dL blood Pb in the female rat offspring at PND31) was found to decrease basal StAR synthesis, but not gonadotropin-stimulated StAR synthesis, suggesting that Pb may not directly affect ovarian responsiveness to gonadotropin stimulation (Srivastava et al., 2004). Instead, Pb may act at the hypothalamic-pituitary level to alter LH secretion, which is necessary to drive StAR production and subsequent sex hormone synthesis. Release of LH and FSH from the pituitary is controlled by gonadotropin-releasing hormone (GnRH). Pb exposure (10 µM, 90 min) in rat brain median eminence cells can block GnRH release (Bratton et al., 1994). Pb may also interfere with release of pituitary hormones through interference with cation-dependent secondary messenger systems that mediate hormone release and storage.

Endocrine disruption may also be a result of altered hormone binding to endocrine receptors. Prenatal and postnatal Pb exposure (20 ppm in drinking water) to rats was able to decrease the number of estrogen, LH, and FSH receptors found in the uterus or ovaries and receptor binding affinity (Wiebe et al., 1988; Wiebe and Barr, 1988). Altered hormone binding ability may be due to the ion binding properties of Pb, resulting in changes in receptor tertiary structure that will disrupt ligand binding. In addition, Pb-induced changes in hormone levels that act as inducing agents for receptor synthesis may affect the number of hormone receptors produced.

Some of these endocrine disrupting effects of Pb have been related to the generation of ROS. Treatment with antioxidants has been able to counteract a number of the endocrine disrupting effects of Pb, including apoptosis and decreased sperm motility and production (Salawu et al., 2009; Shan et al., 2009; Madhavi et al., 2007; Rubio et al., 2006; Wang et al., 2006a; Hsu et al., 1998b). Direct generation of ROS in epididymal spermatozoa was observed after Pb treatment in rats (i.p. 20 or 50 ppm, 6 weeks) (Hsu et al., 1998a). In addition, lipid peroxidation has been observed in Pb-treated rats (i.p. 0.025 ppm, 15 days) (Pandya et al., 2012). Lipid peroxidation in the seminal plasma was significantly increased in a group of Pb-exposed workers with high blood Pb levels (>40 µg/dL) than in unexposed controls (Kasperczyk et al., 2008).

The liver is often associated with the HPG axis due in part to its production of insulin-like growth factor 1 (IGF-1). Children with higher concurrent blood Pb levels (>4 µg/dL) (Huseman et al., 1992) and Pb-exposed animals (blood Pb level of 14 µg/dL) (Pine et al., 2006; Dearth et al., 2002) and gonadal cells (46 ppm Pb exposure) (Kolesarova et al., 2010) have shown a decrease in plasma IGF-1, which may be the result of decreased translation or secretion of IGF-1 (Dearth et al., 2002). IGF-1 also induces LH-releasing hormone release, such that IGF-1 decrements may explain decreased LH and estradiol levels. IGF-1 production is stimulated by growth hormone (GH) secreted from the pituitary gland and could be the result of GH depletion.

A number of studies have revealed that Pb exposure affects the dynamics of growth (see Section 5.8.1). Decreased growth after Pb exposure could be the result of Pb-induced decreased GH levels (Berry et al., 2002; Camoratto et al., 1993; Huseman et al., 1992; Huseman et al., 1987). This decrease in GH could be a result of decreased release of GH releasing hormone (GHRH) from the hypothalamus or disrupted GHRH binding to its receptor, which has been reported in vitro after Pb treatment (IC_{50} free Pb in solution 5.2 $\times 10^{-5}$ µM, 30 minutes) (Lau et al., 1991). GH secretion may also be altered from decreased testosterone, a result of Pb exposure.

5.2.6.2 Hypothalamic-Pituitary-Thyroid Axis

The evidence for the effects of Pb exposure on the hypothalamic-pituitary-thyroid (HPT) axis is mixed. Pb exposure impacts a variety of components in the thyroid hormone system. A number of occupational studies (blood Pb levels >7.3 µg/dL) have shown that elevated blood Pb are associated with lower thyroxine (T_4) (and free T_4 levels) without alteration in triiodothyronine (T_3), suggesting that long-term Pb exposure may depress thyroid function in workers (Dundar et al., 2006; Tuppurainen et al., 1988; Robins et al., 1983). However, animal studies on thyroid hormones have shown mixed results. Pb-exposed cows (blood Pb levels >51 µg/dL) were reported to have an increase in plasma T_3 and T_4 levels (Swarup et al., 2007), whereas mice and chickens manifested decreased serum T_3 concentrations after Pb exposure, which was accompanied by increased lipid peroxidation (Chaurasia et al., 1998; Chaurasia and Kar, 1997). Both decreased serum T_3 and increased lipid peroxidation were restored by vitamin E treatment, suggesting the disruption of thyroid hormone homeostasis could be a result of altered membrane architecture and oxidative stress; however, no data were provided to exclude changes in Pb kinetics as the mechanism of protection (Chaurasia and Kar, 1997).

Decreased T_4 and T_3 may be the result of altered pituitary release of thyroid stimulating hormone (TSH). However, several studies have reported higher TSH levels in high-level Pb-exposed workers (blood Pb levels >39 µg/dL) (Lopez et al., 2000; Singh et al., 2000; Gustafson et al., 1989), which would result in increased T_4 levels. Overall, results on the effects of Pb on the HPT axis are inconclusive.

5.2.7 Cell Death and Genotoxicity

A number of studies have attempted to characterize the genotoxicity of inorganic Pb in human populations, laboratory animals, and cell cultures. Endpoints investigated include DNA damage (single- and double-strand breaks, DNA-adduct formation), mutagenicity, clastogenicity (sister chromatid exchange, micronucleus formation, chromosomal aberrations), and epigenetic changes (changes in gene expression, DNA methylation, mitogenesis). It is important to note that numerous studies have utilized exposure to Pb chromate to investigate genotoxicity endpoints; some studies have specifically attributed the observed increases in DNA damage and clastogenicity to the chromate ion while others have not. Due to the uncertainty regarding whether observed genotoxic effects are due to chromate or Pb in studies using this form of inorganic Pb, only studies utilizing other forms of inorganic Pb (e.g., Pb nitrate, acetate, chloride, sulfate) are discussed below. Overall, evidence indicates that in vitro or in vivo exposure to various Pb compounds can increase risk of genotoxic effects, including DNA damage, clastogenicity, and mutagenicity.

5.2.7.1 DNA Damage

A number of studies in human populations have observed associations between indicators of Pb exposure and increased DNA damage, as measured as DNA strand breaks. Most of these associations have been observed in occupationally-exposed populations (Grover et al., 2010; Minozzo et al., 2010; Shaik and Jamil, 2009; Danadevi et al., 2003; Hengstler et al., 2003; Palus et al., 2003; Fracasso et al., 2002; de Restrepo et al., 2000). Evidence overall was equivocal in regard to how blood Pb levels correlated with DNA damage: Fracasso et al. (2002) observed that DNA damage increased with increasing blood Pb levels (blood Pb levels, <25, 25-35, and >35 µg/dL), whereas Palus et al. (2003) (mean blood Pb level: 50.4 µg/dL [range: 28.2 to 65.5 µg/dL]) and Minozzo et al. (2010) (mean [SD]: 59.43 µg/dL [28.34]) observed no correlation. Hengstler et al. (2003) examined workers exposed to Pb, Cd, and Co and observed that neither blood (mean: 4.4 [IQR: 2.84-13.6] µg/dL) nor air Pb levels (mean: 3.0 [IQR: 1.6-50.0] µg/m^3) were associated with DNA damage when examined alone, but that blood Pb influenced the occurrence of single strand DNA breaks when included in a multiple regression model along with Cd in air and blood and Co in air.

A few studies were found that investigated Pb-induced DNA damage resulting from nonoccupational exposures. Mendez-Gomez (2008) observed that children attending grade schools at close and intermediate distances to a Pb smelter had mean (range) blood Pb levels of 28.6 (11.4 to 47.5) and 19.5 (11.3 to 49.2) µg/dL, respectively, compared to

blood Pb level of 4.6 (0.1 to 8.7) µg/dL for children living distant to the smelter. DNA damage in lymphocytes was higher in children living nearest to the smelter, compared to the children at the intermediate distance, but was not different from children living farthest away from the smelter. Multivariate analysis (which considered children urinary As levels, highest in children farthest from the smelter), revealed no statistically significant associations between DNA damage and blood Pb level. Further, DNA repair ability was also observed to be unrelated to blood Pb levels. Alternatively, Yanez et al. (2003) observed that children living close to a mining complex (mean [range] blood Pb level: 11.6 [3.0 to 19.5] µg/dL) did have higher levels of DNA damage compared to control children who lived further away from the mining facility (mean [range] blood Pb level: 8.3 [3.0 to 25.0] µg/dL).

Pb-induced DNA damage was observed in multiple animal studies. In mice exposed to Pb (blood Pb level of 0.68 µg/dL) via inhalation for up to 4 weeks, differential levels of DNA damage were observed in different organ systems, with only the lung and the liver demonstrating statistically greater DNA damage compared to the respective organ controls after acute exposure (Valverde et al., 2002). Statistically elevated levels of DNA damage were observed in the kidneys, lungs, liver, brain, nasal cavity, bone marrow, and leukocytes of mice exposed to Pb over a period of 4 weeks, although variability was high in all groups. The magnitude of the DNA damage was characterized as weak and did not increase with increasing durations of exposure. In mice given Pb nitrate (0.7 to 89.6 mg/kg) by gavage for 24, 48, or 72 hours, or 1 or 2 weeks, single strand DNA breaks in white blood cells were observed but did not increase with increasing concentration (Devi et al., 2000). The three highest concentrations had responses that were similar in magnitude to each other and were actually lower than the responses to the lower concentrations tested. Xu et al. (2008) exposed mice to 10-100 mg/kg Pb acetate via gavage for four weeks and observed a concentration-dependent increase in DNA single strand breaks in white blood cells that was statistically significant at 50 and 100 mg/kg. The authors characterized the observed DNA damage as severe. Pb nitrate induced DNA damage in primary spermatozoa in rats (blood Pb levels of 19.5 and 21.9 µg/dL) over that in control rats (Nava-Hernandez et al., 2009). The level of DNA damage was not concentration dependent and was comparable in both exposure groups. Narayana and Al-Bader (2011) observed no increase in DNA damage in the livers of rats exposed to 5,000 or 10,000 ppm Pb nitrate in drinking water for 60 days. Interestingly, although the results were not statistically significant and were highly variable within exposure groups, DNA fragmentation appeared to be lower in the exposed animals.

Studies investigating Pb-induced DNA damage in human cell cultures were contradictory. Pb acetate did not induce DNA strand breaks in human HeLa cells when exposed in vitro to 500 µM Pb acetate for 20-25 hours or 100 µM for 0.5-4 hours

(Hartwig et al., 1990; Snyder and Lachmann, 1989). Pb nitrate, administered to lymphoma cells in vitro at 1,000-10,000 µM for 6 hours, did not result in any DNA-protein crosslinks (Costa et al., 1996). Pb acetate was observed by Woźniak and Blasiak (2003) to result in DNA single and double strand breaks in primary human lymphocytes exposed in vitro to 1-100 µM for 1 hour, although the pattern of damage was peculiar. DNA damage was greater in cells exposed to 1 or 10 µM, compared to those exposed to 100 µM. DNA-protein crosslinks were only observed in the 100 µM exposure group, suggesting that the decreased strand breaks observed in the high exposure group may be a result of increased crosslinking in this group. Pasha Shaik et al. (2006) also observed DNA damage in human lymphocytes exposed in vitro to 2,100-3,300 µM Pb nitrate for 2 hours. Although there was a concentration-dependent increase in DNA damage from 2,100-3,300 µM, no statistics were reported and no unexposed control group was included, making it difficult to interpret these results. Gastaldo et al. (2007) observed that in vitro exposure of human endothelial cells to 1-1,000 µM Pb nitrate for 24 hours resulted in a concentration-dependent increase in DNA double strand breaks.

Studies in animal cell lines collectively were equally as ambiguous as those using human cell lines. Zelikoff et al. (1988) and Roy and Rossman (1992) reported that Pb acetate (concentration not stated and 1,000 µM, respectively) did not induce single or double DNA strand breaks or DNA-protein or DNA-DNA crosslinks in CHV79 cells. However, both Xu et al. (2006) and Kermani et al. (2008) reported Pb acetate-induced DNA damage in undifferentiated PC12 cells exposed to 0.1, 1, or 10 µM for 24 hours; and in bone marrow mesenchymal stem cells exposed to 60 µM for 48 hours, respectively. Wedrychowski et al. (1986) reported that DNA-protein crosslinks were induced in a concentration-dependent manner in hepatoma cells exposed to 50-5,000 µM Pb nitrate for 4 hours. Pb acetate and Pb nitrate increased the incidence of nick translation in CHV79 cells when a bacterial DNA polymerase was added.

Pb exposure has also been shown to inhibit DNA repair mechanisms. Pb acetate did not induce single strand DNA breaks in HeLa cells exposed to 500 µM for 20-25 hours (Hartwig et al., 1990). However, exposure to both Pb acetate and UV light resulted in increased persistence of UV-induced strand breaks, compared with exposure to UV light alone. Similar effects were seen in hamster V79 cells: UV-induced mutation rates and SCE frequency was exacerbated by co-incubation with Pb acetate. Taken together, these data suggest that Pb acetate interferes with normal DNA repair mechanisms triggered by UV exposure alone. Pb nitrate was observed to affect different DNA double strand break repair pathways in human endothelial cells exposed in vitro to 100 µM for 24 hours. Exposure to Pb inhibited nonhomologous end joining repair, but increased two other repair pathways, MRE11-dependent and Rad51-related repair (Gastaldo et al., 2007).

Interestingly, in contrast to the above studies, exposure of lung carcinoma cells to 100, 300, or 500 µM Pb acetate for 24 hours resulted in an increase in nucleotide excision repair efficiency (Li et al., 2008a). Roy and Rossman (1992) observed an increase in UV-induced mutagenicity when CHV79 cells were co-exposed to 400 µM Pb acetate (a nonmutagenic concentration of Pb acetate), indicating an inhibition of DNA repair. Treatment of Chinese hamster ovary cells to 0.5-500 µM Pb acetate resulted in a concentration-dependent accumulation of apurinic/apyrimidinic site incision activity, indicating that DNA repair was diminished (McNeill et al., 2007).

5.2.7.2 Mutagenicity

Only one human study was found that investigated Pb-induced mutagenicity. Van Larebeke et al. (2004) investigated the frequency of mutations in the hypoxanthine phosphoribosyltransferase (HPRT) gene in Flemish women without occupational exposures to Pb or to a number of other heavy metals and organic contaminants. Higher blood Pb level (10th-90th percentile:1.6 to 5.2 µg/dL) was associated with greater HPRT mutation frequency than found in the total population. Also, women with high blood Pb levels (i.e., greater than the population median, not reported) demonstrated a greater mutation frequency compared to women with lower blood Pb levels.

Pb-induced mutagenicity was investigated in a few studies using human cell cultures. Ye (1993) exposed human keratinocytes to 100 µM to 1×10^5 µM Pb acetate for 2-24 hours. This study did not measure HPRT mutations directly, but rather measured the amount of tritium (^3H) incorporated into DNA as an indicator of mutation. In the presence of 6-thioguanine, tritium incorporation was increased in exposed cells, indicating weak mutagenicity. Hwua and Yang (1998) reported that Pb acetate was not mutagenic in human foreskin fibroblasts exposed to 500-2,000 µM for 24 hours. Pb acetate remained nonmutagenic in the presence of 3-aminotriazole, a catalase inhibitor, indicating that oxidative metabolism did not play a part in potential mutagenicity of Pb. Exposure to Pb acetate alone did not induce mutagenicity in lung carcinoma cells (100-500 µM for 24 hours) or fibroblasts (300-500 µM for 24 hours) (Li et al., 2008a; Wang et al., 2008c). However, pretreatment with PKC inhibitors before Pb treatment did result in statistically significant increases in mutagenicity in both cell lines.

Results from investigations into Pb-induced mutagenicity using animal cell lines were as equivocal as were the findings from human cell line studies, although the mixed findings may be reflective of specific Pb compounds used. Pb acetate was observed to be nonmutagenic (HPRT assay) in CHV79 cells exposed to 1-25 µM of the compound for 24 hours (Hartwig et al., 1990), but elicited a mutagenic response in CHV79 cells (gpt

assay) exposed to 1,700 µM for 5 days (Roy and Rossman, 1992). Pb acetate was observed to be nonmutagenic (HPRT assay) in Chinese hamster ovary cells exposed to 5 µM for 6 hours (McNeill et al., 2007). The implication of mutagenicity in the latter study is complicated by the concurrent observation of severe cytotoxicity at the same concentration. Pb nitrate was alternatively found to be nonmutagenic in CHV79 cells (gpt assay) exposed to 0.5-2,000 µM for 5 days (Roy and Rossman, 1992) but mutagenic in the same cell line (HPRT assay) exposed to 50-5,000 µM for 5 days (Zelikoff et al., 1988). However, mutagenicity was only observed at 500 µM, and was higher than that observed at higher Pb concentrations. Pb sulfate was also observed to be mutagenic in CHV79 cells (HPRT assay) exposed to 100-1,000 µM for 24 hours, but as with Pb nitrate, it was not concentration-dependent (Zelikoff et al., 1988). Pb chloride was the only Pb compound tested in animal cell lines that was consistently mutagenic: three studies from the same laboratory observed concentration-dependent mutagenicity in the gpt assay in Chinese hamster ovary cells exposed to 0.1-1 µM Pb chloride for one hour (Ariza and Williams, 1999; Ariza et al., 1998; Ariza and Williams, 1996).

5.2.7.3 Clastogenicity

Clastogenicity is the ability of a compound to induce chromosomal damage, and is commonly observed as sister chromatid exchange (SCE), micronuclei formation, or incidence of chromosomal aberrations (i.e., breaks or gaps in chromosomes). Pb has been shown to increase sister chromatid exchange, micronuclei formation, and chromosomal aberrations in human populations, exposed animal models, and in vitro experiments.

Sister Chromatid Exchange

An association between blood Pb levels (means: 10.48 - 86.9 µg/dL) and sister chromatid exchange (SCE) was observed in a number of occupational studies (Wiwanitkit et al., 2008; Duydu et al., 2005; Palus et al., 2003; Duydu et al., 2001; Pinto et al., 2000; Bilban, 1998; Anwar and Kamal, 1988; Huang et al., 1988). In most studies that attempted to investigate the concentration-response relationship in workers, no association was observed between increasing blood Pb levels and the number of SCE (Palus et al., 2003; Duydu et al., 2001; Pinto et al., 2000). However, Huang et al. (1988) did observe increased SCE in exposed workers in the two highest blood Pb groups (52.1 and 86.9 µg/dL), with a statistically significant association observed in the 86.9 µg/dL group. Pinto et al. (2000) did report an association with duration of exposure (range of years exposed: 1.6-40). Two studies reported no correlation between occupational exposure to Pb and number of SCE (Rajah and Ahuja, 1996; Rajah and Ahuja, 1995).

Mielzynska et al. (2006) found no association between blood Pb level and SCEs in children in Poland. Children had an average blood Pb level of 7.69 µg/dL and 7.87 SCEs/cell.

Pb exposure has been observed to induce SCEs in multiple laboratory animal studies. In mice treated with up to 100 mg/kg Pb acetate i.p., Pb induced SCEs with 50 and 100 mg/kg (Fahmy, 1999). Pb nitrate, also administered i.p. induced the formation of increased SCE levels in a concentration-dependent manner (10-40 mg/kg) in the bone marrow of exposed mice (Dhir et al., 1993). Nayak et al. (1989b) treated pregnant mice with 100-200 mg/kg Pb nitrate via i.v. injection and observed an increase in the number of SCE in dams at 150 and 200 mg/kg; no increases in SCE levels were observed in the fetuses. Tapisso et al. (2009) treated rats with 21.5 mg/kg Pb acetate (1/10th the LD_{50}) via i.p. injection on alternating days for 11 or 21 days, for a total of 5 or 10 treatments. Induction of SCE in the bone marrow of exposed rats was increased over controls in a statistically significant duration-dependent manner. It is important to note that all of these studies utilized an injection route of exposure that may not be relevant to routes of exposure in the human population (e.g., air, drinking water exposure).

Few studies were found that investigated SCE formation due to Pb exposure in human cell lines. Statistically significant, concentration-dependent increases in SCE were observed in human lymphocytes obtained from a single donor when incubated with 1, 5, 10, or 50 µM Pb nitrate (Üstundag and Duydu, 2007). Melatonin and N-acetylcysteine were reported to ameliorate these effects, indicating Pb may induce increases in SCE levels through increased oxidative stress. Pb chloride was also observed to increase SCE levels in human lymphocytes exposed to 3 or 5 ppm (Turkez et al., 2011).

Evidence from studies investigating SCE in rodent cells was more equivocal than that in human cells. Pb sulfate, acetate, and nitrate were found not to induce SCE in CHV79 cells (Hartwig et al., 1990; Zelikoff et al., 1988). Both of these studies only examined 25-30 cells per concentration, reducing their power to detect Pb-induced increases in SCE levels. Cai and Arenaz (1998), on the other hand, used 100 cells per treatment and observed that exposure to 0.05-1 µM Pb nitrate for 3-12 hours resulted in a weak, concentration-dependent increase in SCE levels in Chinese hamster ovary cells. Lin et al. (1994) also observed a concentration-dependent increase in SCE levels in Chinese hamster cells exposed to 3-30 µM Pb nitrate for 2 hours.

Micronucleus Formation

Pb-induced micronucleus formation was observed in numerous occupational studies (Grover et al., 2010; Khan et al., 2010b; Minozzo et al., 2010; Shaik and Jamil, 2009; Minozzo et al., 2004; Palus et al., 2003; Vaglenov et al., 2001; Pinto et al., 2000; Bilban, 1998; Vaglenov et al., 1998). Pinto et al. (2000) observed increased micronuclei in exposed workers with an average blood Pb level of 10.48 µg/dL compared with unexposed controls. In studies investigating the correlation between blood Pb levels and micronucleus formation, no association was observed (Minozzo et al., 2010; Minozzo et al., 2004; Palus et al., 2003; Pinto et al., 2000), although Pinto et al. (2000), Grover et al. (2010), and Minozzo et al. (2010) did report an association between micronuclei formation and duration of exposure. Mielzynska et al. (2006) investigated micronucleus formation in a nonworker population and reported a statistically significant positive correlation between blood Pb levels and micronuclei frequency in children in Poland. Children, with an average blood Pb level of 7.69 µg/dL, were observed to have 4.44 micronucleated cells per 1,000 cells analyzed. Children with blood Pb levels greater than 10 µg/dL had significantly more micronucleated cells than did children with blood Pb levels less than 10 µg/dL.

Micronucleus formation in response to Pb exposure has been observed in rodent animal studies. Celik et al. (2005) observed that exposure of female rats to Pb acetate (140, 250, or 500 mg/kg once per week for 10 weeks) resulted in statistically significant increases in numbers of micronucleated polychromatic erythrocytes (PCEs) compared to controls. Similarly, Alghazal et al. (2008b) exposed rats to Pb acetate (100 ppm daily for 125 days) and observed statistically significant increases in micronucleated PCEs in both sexes. Tapisso et al. (2009) treated rats with Pb acetate (21.5 mg/kg; 1/10th the LD_{50}) via i.p. injection on alternating days for 11 or 21 days, for a total of 5 or 10 exposures. Formation of micronuclei in the bone marrow of exposed rats was increased over formation in controls in a significant duration-dependent manner. Two further studies investigated formation of micronuclei in the bone marrow of exposed mice: Roy et al. (1992) treated mice with Pb nitrate (10 or 20 mg/kg, i.p.) and observed a concentration-dependent increase in micronuclei, whereas Jagetia and Aruna (1998) observed an increase in micronuclei in mice treated with Pb nitrate (0.625-80 mg/kg, i.p.), though the increase was not concentration-dependent. Mice exposed to Pb acetate (0.1 µg/L via drinking water, a more environmentally relevant route of exposure, for 90 days) had statistically significant increases in micronucleated PCEs (Marques et al., 2006).

A few studies were found that reported increased micronucleus formation in human cell lines treated with Pb. Concentration-dependent micronucleus formation was observed in human lymphocytes when exposed in vitro to either 1, 5, 10, or 50 µM Pb nitrate or 3 or 5 ppm Pb chloride (Turkez et al., 2011; Üstundag and Duydu, 2007). Gastaldo et al.

(2007) also observed a concentration-dependent increase in micronuclei in human endothelial cells exposed in vitro to 1-1,000 µM Pb nitrate for 24 hours. Animal cell culture studies investigating micronuclei formation produced contrasting results. One study observed that micronuclei were not induced in Chinese hamster cells exposed to 3-30 µM Pb nitrate for 2 hours (Lin et al., 1994), whereas the other observed that Pb acetate induced a concentration-dependent increase in Chinese hamster cells when administered at 0.03-10 µM for 18 hours (Bonacker et al., 2005).

Chromosomal Aberrations

Chromosomal aberrations (e.g., chromosome breaks, nucleoplasmic bridges, di- and a-centric chromosomes, and rings) were examined in a number of occupational studies (Grover et al., 2010; Shaik and Jamil, 2009; Pinto et al., 2000; Bilban, 1998; De et al., 1995; Huang et al., 1988). No correlation was observed between increasing blood Pb level and the number of chromosomal aberrations, although an association was observed between duration of exposure and chromosomal damage (Grover et al., 2010; Pinto et al., 2000). Other studies reported no association between occupational exposure to Pb and chromosomal aberrations (Anwar and Kamal, 1988; Andreae, 1983). Smejkalova (1990) observed greater chromosomal damage and aberrations in children living in a heavily Pb-contaminated area of Czechoslovakia compared with children living in an area with less contamination, although the difference between the two areas was not statistically significant. Blood Pb levels were comparable between children living in the Pb-contaminated area and children living in the less contaminated area (low 30s versus high 20s µg/dL, respectively), indicating there may not be enough of a dose contrast to detect a significant difference in aberration rates.

The majority of animal studies investigating Pb-induced genotoxicity focused on the capacity of Pb to produce chromosomal damage. Fahmy (1999) treated mice with Pb acetate (25-400 mg/kg i.p.), either as a single dose or repeatedly for 3, 5, or 7 days. Chromosomal damage was observed to increase in bone marrow cells (100-400 mg/kg) and spermatocytes (50-400 mg/kg) in a concentration-dependent manner after both dosing regimens. Pb nitrate was also observed to produce concentration-dependent chromosomal damage in mice treated i.p. to a single dosage of 5, 10, or 20 mg/kg (Dhir et al., 1992b). In a similar experiment, Dhir et al. (1990) treated mice with Pb nitrate (10, 20, or 40 mg/kg) and saw an increase in chromosomal aberrations, although there was no concentration-dependent response as the response was similar in all concentrations tested. Nayak et al. (1989b) treated pregnant mice with Pb nitrate (100, 150, or 200 mg/kg via i.v. injection) and observed no chromosomal gaps or breaks in dams or fetuses but did report some karyotypic chromosomal damage and weak aneuploidy at the low dose. In a similar experiment, low levels of chromosomal aberrations were observed in dams and

fetuses injected with Pb nitrate (12.5, 50, or 75 mg/kg), but there was no concentration-dependent response reported and few cells were analyzed (Nayak et al., 1989a). In rats given Pb acetate (2.5 mg/100 g body weight, i.p. daily for 5-15 days or 10-20 mg/100 g once and analyzed after 15 days), Pb-induced chromosomal aberrations were observed (Chakraborty et al., 1987). The above studies all are limited by the use of a route of exposure that may not be relevant to human environmental exposures. However, studies utilizing oral exposures also observed increases in chromosomal damage. Aboul-Ela (2002) exposed mice to Pb acetate (200 or 400 mg/kg by gavage for 5 days) and reported that chromosomal damage was present in the bone marrow cells and spermatocytes of animals exposed to both concentrations. Dhir et al. (1992a) also observed a concentration-dependent increase in chromosomal damage in mice exposed via gavage, albeit at much lower concentrations: either 5 or 10 mg/kg. Nehez et al. (2000) observed a Pb-induced increase in aneuploidy and percent of cells with damage after exposure to 10 mg/kg administered by gavage 5 days a week for 4 weeks. In the only study that investigated dietary exposure, El-Ashmawy et al. (2006) exposed mice to 5,000 ppm Pb acetate in feed, and observed an increase in abnormal cells and frequency of chromosomal damage.

In the few studies that investigated the capacity of Pb to induce chromosomal damage in human cell lines, Pb exposure did not induce chromosomal damage. Wise et al. (2005; 2004) observed that Pb glutamate was not mutagenic in human lung cells exposed in vitro to 250-2,000 µM for 24 hours. Pasha Shaik et al. (2006) observed that Pb nitrate did not increase chromosomal aberrations in primary lymphocytes (obtained from healthy volunteers) when incubated with 1,200 or 2,000 µM for 2 hours. Studies utilizing animal cell lines generally supported the finding of no Pb-induced chromosomal damage in human cell lines. Pb nitrate was found to induce no chromosomal damage in Chinese hamster ovary cells exposed to 500-2,000 µM for 24 hours (Wise et al., 1994), 3-30 µM for 2 hours (Lin et al., 1994), or 0.05-1 µM for 3-12 hours (Cai and Arenaz, 1998). Wise et al. (1994) did observe increased chromosomal damage in Chinese hamster ovary cells exposed to 1,000 µM Pb glutamate for 24 hours, but did not see any damage in cells exposed to higher concentrations (up to 2,000 µM).

5.2.7.4 Epigenetic Effects

Epigenetic effects are heritable changes in gene expression resulting without changes in the underlying DNA sequence. A prime example of an epigenetic effect is the abnormal methylation of DNA, which could lead to altered gene expression and cell proliferation and differentiation. Possible indications of Pb-induced epigenetic changes include alterations in methylation patterns in exposed rats, and alterations in mitogenesis and cell proliferation in exposed humans and animals, as well as human and animal cell cultures.

DNA Methylation

A single i.v. injection of Pb nitrate (75 µmol/kg) resulted in global hypomethylation of hepatic DNA in rats (Kanduc et al., 1991). The observed hypomethylation in the liver was associated with an increase in cell proliferation. A few additional studies in humans observed that higher bone Pb levels were associated with lower global DNA methylation patterns in adults and cord blood of newborns (Wright et al., 2010; Pilsner et al., 2009). Hypomethylation specifically is associated with increased gene expression. Changes in DNA methylation patterns could potentially lead to dysregulation of gene expression and altered tissue differentiation.

Mitogenesis

Conflicting results have been reported regarding Pb-induced effects on mitogenesis, with both increased and decreased cell growth and mitogenesis. A discernible pattern of effects is difficult to detect when analyzing effects across human, in vivo animal, and in vitro studies. Only a few studies have investigated the mitogenic effects of Pb exposure in human populations indirectly by examining mitogenesis or the induction of cell proliferation, which can be a consequence of epigenetic changes. These studies (Minozzo et al., 2010; Minozzo et al., 2004; Rajah and Ahuja, 1995) reported reduced mitogenesis in two groups of Pb-exposed workers compared with unexposed controls (mean blood Pb levels: 35.4 µg/dL, 59.4 µg/dL, and not reported, respectively). The observation of decreased cell division in exposed workers may indicate that cells suffered DNA damage and died during division, or that division was delayed to allow for DNA repair to occur. It is also possible that Pb exerts an aneugenic effect and arrests the cell cycle.

Many studies have investigated the ability of Pb to induce mitogenesis in animal models, and have consistently shown that Pb nitrate can stimulate DNA synthesis and cell proliferation in the liver of animals treated with 100 µM Pb per kg body weight, via i.v. injection (Nakajima et al., 1995; Coni et al., 1992; Ledda-Columbano et al., 1992; Columbano et al., 1990; Columbano et al., 1987). Shinozuka et al. (1996) observed that

Pb-induced hepatocellular proliferation was similar in magnitude to that induced by TNF-α at 100 μM/kg; and Pb was observed to induce TNF-α in glial and nerve cells in mice (and NF-κB, TNF-α, and iNOS in rat liver cells) from mice treated with Pb at 12.5 mg/kg and 100 μmol/kg, respectively (Cheng et al., 2002; Menegazzi et al., 1997). The only study that examined Pb exposure via inhalation (Pb acetate, 10,000 μM for 4 weeks) resulted in increased cellular proliferation in murine lungs (Fortoul et al., 2005).

Extensive research has been conducted investigating the potential effects of Pb on mitogenesis in human and animal cell cultures. In human cell cultures, Pb acetate inhibited cell growth in hepatoma cells (0.1-100 μM for 2-6 days) (Heiman and Tonner, 1995) and primary oligodendrocyte progenitor cells (1 μM for 24 hours) (Deng and Poretz, 2002) but had no observable effects on growth in glioma cells (0.01-10 μM for 12-72 hours) (Liu et al., 2000). Pb glutamate had no effect on cell growth in human lung cells in vitro, but did increase the mitotic index (250-1,000 μM exposure for 24 hours) (Wise et al., 2005). The increase in the mitotic index was attributed to an arrest of the cell cycle at M-phase, and was not attributed to an actual increase of cell growth and proliferation. Gastaldo et al. (2007) also reported S and G2 cell cycle arrests in human endothelial cells following exposure to 100 μM Pb nitrate for 24 hours. Conflicting results with regard to DNA synthesis were reported, with a concentration-dependent inhibition of DNA synthesis reported in hepatoma cells (1-100 μM for 72 hours) (Heiman and Tonner, 1995), but an induction of synthesis observed in astrocytoma cells (1-50 μM for 24 hours) (Lu et al., 2002).

In rat fibroblasts and epithelial cells, Pb acetate, Pb chloride, Pb oxide, and Pb sulfate were all observed to inhibit cell growth (10-1,000 μM for 1-7 days and 0.078-320 μM for 48 hours, respectively) (Iavicoli et al., 2001; Apostoli et al., 2000). Iavicoli et al. (2001) observed that in addition to inhibiting cell growth in rat fibroblasts, Pb acetate caused GS/M and S-phase arrest. Pb acetate decreased cell proliferation in mouse bone marrow mesenchymal stem cells when administered at 20-100 μM for 48 hours (Kermani et al., 2008). Pb nitrate was alternatively reported to increase (Lin et al., 1994) and decrease (Cai and Arenaz, 1998) the mitotic index in Chinese hamster ovary cells exposed to 1 μM Pb nitrate. Lin et al. (1994) did not consider cell cycle arrest when measuring the mitotic index and did not observe a decrease at higher concentrations; in fact, the highest concentration tested, 30 μM, had a mitotic index equal to that in the untreated control cells.

5.2.7.5 Gene Expression

A few animal studies have investigated the ability of Pb exposure to alter gene expression in regard to phase I and II metabolizing enzymes. Suzuki et al. (1996) treated rats with Pb acetate or Pb nitrate (100 μg/kg via i.p. injection) and observed an induction of GST-P with both Pb compounds. The induction of GST-P by Pb was observed to occur on the transcriptional level and to be dependent on the direct activation of the cis-element GPEI enhancer. Degawa et al. (1993) reported that Pb nitrate (20, 50, or 100 μmol/kg, via i.v.) selectively inhibited CYP1A2 levels. Pb was shown not to inhibit CYP1A2 by direct enzyme inhibition, but rather to decrease the amount of CYP1A2 mRNA. In contrast, Korashy and El Kadi (2004) observed that exposure of murine hepatoma cells to Pb nitrate (10-100 μM for 24 hours) increased the amount of CYP1A1 mRNA while not influencing the activity of the enzyme. NAD(P)H:quinone oxidoreductase and GST Ya activities and mRNA levels were increased after exposure to Pb. Incubation of primary human bronchial epithelial cells with Pb acetate (500 μg/L for 72 hours) resulted in the up-regulation of multiple genes associated with cytochrome P450 activity, glutathione metabolism, the pentose phosphate pathway, and amino acid metabolism (Glahn et al., 2008).

Additional animal studies provide further evidence that exposure to Pb compounds can perturb gene expression. Zawia and Harry (1995) investigated whether the observed Pb-induced disruption of myelin formation in rat pups exposed postnatally was due to altered gene expression. In pups exposed to 2,000 ppm Pb acetate via lactation from PND1-PND20, the expression of proteolipid protein, a major structural constituent of myelin, was elevated (statistically significant) at PND20, compared to controls. The expression of another structural element of myelin (myelin basic protein) was similarly elevated in exposed animals, although not significantly so. The expression of both genes returned to control levels 5 days following the termination of exposure. These data suggest that altered gene expression in structural myelin proteins due to Pb exposure may be responsible for observed alterations in abnormal conduction of nerve impulses. Long et al. (2011) investigated the Pb-induced increase in ABCC5, an ATP-binding cassette transporter, in embryonic and adult zebrafish. In the initial in vitro portion of the study, exposure of zebrafish fibroblasts to 20 μM Pb nitrate for 24 hours significantly increased the induction of ABBC5 mRNA 2.68-fold over controls. Similar levels of induction were observed when embryonic zebrafish were exposed to 5 μM for 24 to 96 hours; specifically, induction of ABCC5 was seen in the livers of developing embryos. In adult fish, induction of ABCC5 was observed in the brains, intestines, and kidneys of exposed fish, but a decrease was found in their livers. Induction of ABCC5 in adult fish was observed to attenuate the toxicity of Cd (but not Hg or As); however, in developing embryos, the attenuation of Pb-induced toxicity was not investigated. These findings

indicate that increased expression of ABCC5 due to heavy metal exposure may play a part in cellular defense mechanisms.

5.2.7.6 Apoptosis

Occupational exposure to Pb and induction of apoptosis in various cell types was investigated in a few studies. The study that directly measured apoptosis reported that exposure to Pb increased apoptosis of lymphocytes compared to nonexposed controls (Minozzo et al., 2010), whereas the others reported that two early indicators of apoptosis, karyorrhexis and karyolysis, were elevated in occupationally exposed workers (Grover et al., 2010; Khan et al., 2010b). Pb nitrate was also observed to induce apoptosis in the liver of exposed animals (Columbano et al., 1996; Nakajima et al., 1995). Apoptosis was observed in rat fibroblasts exposed in vitro to Pb acetate and rat alveolar macrophages exposed to Pb nitrate (Iavicoli et al., 2001; Shabani and Rabbani, 2000). Observation of Pb-induced apoptosis may represent the dysregulation of genetically-controlled cell processes and tissue homeostasis.

5.2.8 Summary

The diverse health effects of Pb are mediated through multiple, interconnected modes of action. Each of the modes of action discussed here has the potential to contribute to the development of a number of Pb-induced health effects (Table 5-2). While this section draws from earlier literature as well as newer lines of evidence, the inclusion of recent evidence does not qualitatively change the previous conclusions regarding individual modes of action. Rather, the more recent evidence agrees with, and thus strengthens these conclusions. Evidence for the majority of these modes of action is observed with blood Pb levels in humans ranging between 2 and 17 µg/dL, with supporting evidence from animal and in vitro assays. As many of these studies examined adults, with likely higher past than current Pb exposures, uncertainty exists as to the Pb exposure level, duration, frequency, and timing associated with these modes of action. The blood Pb levels or in vitro concentrations presented in Table 5-2 reflect the current evidence for these modes of action and are not intended to convey conclusions regarding specific thresholds. Also, the data presented in this table do not inform the exposure frequency and duration required to elicit a particular MOA.

Table 5-2 MOAs, their related health effects, and information on concentrations eliciting the MOAs.

Mode of Action [Related Health Effects (ISA Section)]	Concentrations or Doses (Conditions)[a]	
	Blood Pb	Dose
Altered Ion Status [All Health Effects of Pb]	3.5 µg/dL (Mean in cord blood; association with cord blood Ca^{2+}ATPase pump activity) Huel et al. (2008)	0.00005 µM free Pb^{2+} (In vitro; 30 minutes; calmodulin activation assay) Kern et al. (2000)
Protein Binding [Renal (5.5), Hematological Effects (5.7)]	17.0 µg/dL (Concurrent mean in adult workers with wildtype metallothionein expression; increased BP susceptibility) Chen et al. (2010a)	50 µM Pb glutamate (In vitro; 24 hours; increased nuclear protein in neurological cell) Klann and Shelton (1989)
Oxidative Stress [All Heath Effects of Pb]	5.4 µg/dL (Concurrent mean in adult male workers; decreased CAT activity in blood) Conterato et al. (In Press)	0.1 µM Pb acetate (In vitro; 48 hours; decreased cellular GSH in neuroblastoma cells) Chetty et al. (2005)
Inflammation [Nervous System (5.3), Cardiovascular (5.4), Renal (5.5), Immune (5.6), Respiratory (5.9.6), Hepatic (5.9.1)]	Among males with concurrent blood Pb ≥ 2.5 µg/dL (Increased serum TNF-α and blood WBC count) Kim et al. (2007)	0.01 µM Pb acetate (In vitro; 48 hours; increased cellular PGE_2 in neuroblastoma cells) Chetty et al. (2005)
Endocrine Disruption [Reproductive and Developmental Effects (5.8), Endocrine System (5.9.3), Bone and Teeth (5.9.4)]	1.7 µg/dL (lowest level at which a relationship could be detected in adult women with both ovaries removed; increased serum FSH) Krieg (2007)	10 µM Pb nitrate (In vitro; 30 minutes; displaced GHRH binding to rat pituitary receptors) Lau et al. (1991)
Cell Death/Genotoxicity [Cancer (5.10), Reproductive and Developmental Effects (5.8), Bone and Teeth (5.9.4)]	3.3 µg/dL (concurrent median in adult women; increased rate of HPRT mutation frequency) Van Larebeke et al. (2004)	0.03 µM Pb acetate (In vitro; 18 hours; increased formation of micronuclei) Bonacker et al. (2005)

[a]This table provides examples of studies that report effects with low Pb dosages or concentrations; they are not the full body of evidence used to characterize the weight of the evidence. In addition, the levels cited are reflective of the data and methods available and do not imply that these modes of action are not acting at lower Pb exposure or blood Pb levels or that these doses represent the threshold of the effect. Additionally, the blood concentrations and doses (indicating Pb concentrations from in vitro systems) refer to the concentrations and doses at which these modes of action were observed. While the individual modes of action are related back to specific health effects sections (e.g., Nervous System, Cardiovascular), the concentrations and doses given should not be interpreted as levels at which those specific health effects occur.

The alteration of cellular ion status (including disruption of Ca^{2+} homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) appears to be the major unifying mode of action underlying all subsequent modes of action (Figure 5-1). Pb is well characterized to interfere with endogenous Ca^{2+} homeostasis (necessary as a cell signal carrier mediating normal cellular functions). $[Ca^{2+}]_i$ has been shown to increase after Pb exposure in a number of cell types including bone, erythrocytes, brain cells, and white blood cells, due to the increased flux of extracellular Ca^{2+} into the cell. This disruption of ion transport is due in part to the alteration of the activity of transport channels and proteins, such as Na^+/K^+ATPase and voltage-gated Ca^{2+} channels. Pb can interfere with these proteins through direct competition between Pb and the native metals present in the protein metal binding

domain or through disruption of proteins important in Ca^{2+}-dependent cell signaling, such as PKC or calmodulin.

Disruption of ion transport not only leads to altered Ca^{2+} homeostasis, but it can also result in perturbed neurotransmitter function. Pb has been shown to displace metal ions, (such as Zn^{2+}, Mg^{2+}, and Ca^{2+}) from proteins due to the flexible coordination number of Pb and multiple ligand binding ability, leading to abnormal conformational changes in proteins and altered protein function. Evidence for this metal ion displacement and protein perturbation has been shown at t 10^{-6} µM concentrations of Pb. Additional effects of altered cellular ion status are the inhibition of heme synthesis and decreased cellular energy production due to perturbation of mitochondrial function.

Although Pb can bind to proteins within cells through interactions with side group moieties, thus potentially disrupting cellular function, protein binding of Pb may represent a mechanism by which cells protect themselves against the toxic effects of Pb. Intranuclear and intracytosolic inclusion body formation has been observed in the kidney, liver, lung, and brain following Pb exposure. A number of unique Pb binding proteins have been detected, constituting the observed inclusion bodies. The major Pb binding protein in blood is ALAD with carriers of the ALAD-2 allele potentially exhibiting higher Pb binding affinity. Additionally, metallothionein is an important protein in the formation of inclusion bodies and mitigation of the toxic effects of Pb.

A second major mode of action of Pb is its role in the development of oxidative stress, due in many instances to the antagonism of normal metal ion functions. The origin of oxidative stress produced after Pb exposure is likely a multipathway process, resulting from oxidation of δ-ALA, NAD(P)H oxidase activation, membrane and lipid peroxidation, and antioxidant enzyme depletion. Through the inhibition of δ-ALAD (due to displacement of Zn by Pb), accumulated δ-ALA goes through an auto-oxidation process to produce ROS. Additionally, Pb can induce the production of ROS through the activation of NAD(P)H oxidase. Pb-induced ROS can interact with membrane lipids to cause a membrane and lipid peroxidation cascade. Enhanced lipid peroxidation can also result from Pb potentiation of Fe^{2+} initiated lipid peroxidation and alteration of membrane composition after Pb exposure. Increased Pb-induced ROS can also sequester and inactivate biologically active NO, leading to the increased production of the toxic product nitrotyrosine, increased compensatory NOS, and decreased sGC protein. Pb-induced oxidative stress not only can result from increased ROS production but also through the alteration and reduction in activity of the antioxidant defense enzymes. The biological actions of a number of these enzymes are antagonized due to the displacement of the protein functional metal ions by Pb.

In a number of organ systems, Pb-induced oxidative stress is accompanied by misregulated inflammation. Pb exposure can modulate inflammatory cell function, production of pro-inflammatory cytokines and metabolites, inflammatory chemical messengers, and pro-inflammatory signaling cascades. Cytokine production is skewed toward the production of pro-inflammatory cytokines like TNF-α and IL-6 as well as toward the promotion of a Th2 response and suppression of a Th1 response accompanied by decreased production of related cytokines.

Evidence indicates that Pb is a potent endocrine disrupting chemical. Pb can disrupt the HPG axis evidenced by altered serum hormone levels, such as FSH, LH, testosterone, and estradiol. Pb can interact with the hypothalamic-pituitary level hormone control causing a decrease in pituitary hormones, alteration of growth dynamics due to decreased IGF-1, inhibition of LH secretion, and reduction in StAR protein. Pb has also been shown to alter hormone receptor binding likely due to interference of metal cations with secondary messenger systems and receptor ligand binding and through generation of ROS. Pb also may disrupt the HPT axis by alteration of a number of thyroid hormones, possibly due to oxidative stress. However, the results of these studies investigating HPT are mixed.

The association of Pb with increased genotoxicity and cell death has been investigated in humans, animals, and cell models. Occupational Pb exposure in humans has been associated with increased DNA damage; however, lower blood Pb and exposure levels have been associated with these effects in experimental animals and cells. While not entirely consistent, a number of studies reported decreased repair processes following Pb exposure. There is evidence of mutagenesis and clastogenicity in highly-exposed humans; however, weak evidence has been shown in animals and cell based systems. Human occupational studies provide limited evidence for micronucleus formation (blood Pb levels >10 µg/dL) and are supported by Pb-induced effects in both animal and cell studies at higher exposure levels. Animal studies have also provided evidence for Pb-induced chromosomal aberrations. The observed increases in clastogenicity may be the result of increased oxidative damage to DNA due to Pb exposure, as co-exposures with antioxidants ameliorate the observed toxicities. Limited evidence of epigenetic effects is available, including abnormal DNA methylation, mitogenesis, and gene expression. Pb may alter gene expression by displacing Zn from multiple transcriptional factors, thus perturbing their normal cellular activities. Consistently positive results have provided evidence of increased apoptosis following Pb exposure.

Similar to Pb, other polyvalent metal ions (e.g., Cd, Cr, Be, Ba, Se, Sr, As, Al, Cu) have demonstrated molecular mimicry and displacement of biological cations (Garza et al., 2006). In this manner, these metal ions share with Pb a common central mode of action of

disruption of ion status. Specifically, these metals have been shown to disrupt cellular processes as diverse as Ca^{2+} homeostasis, cell signaling, neurotransmitter release, cation membrane channel function, protein-DNA binding, and cellular membrane structure (Pentyala et al., 2010; Huang et al., 2004; Atchison, 2003; Jehan and Motlag, 1995; Richardt et al., 1986; Cooper and Manalis, 1984; Habermann et al., 1983). Additionally, presumably through their shared central mode of action, some of these metal ions also display corresponding downstream modes of actions such as oxidative stress, apoptosis, and genotoxicity (Jomova and Valko, 2011; Jomova et al., 2011; Matović et al., 2011; Agarwal et al., 2009; Méndez-Gómez et al., 2008; Rana, 2008; Hengstler et al., 2003).

Overall, Pb-induced health effects can occur through a number of interconnected modes of action that generally originate with the alteration of ion status.

5.3 Nervous System Effects

5.3.1 Introduction

The 2006 Pb AQCD concluded that the "overall weight of the available evidence provides clear substantiation of neurocognitive decrements being associated in young children with blood-Pb concentrations…" (U.S. EPA, 2006b). This conclusion was based on evidence from several prospective and cross-sectional epidemiologic studies conducted in diverse populations with adjustment for potential confounding by socioeconomic status (SES), parental intelligence, and parental caregiving quality and stimulation. The association between blood Pb levels and cognitive function decrements was substantiated in an international pooled analysis of children, ages 4.8 to 10 years, participating in seven prospective studies (Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie, Australia; and Kosovo, Yugoslavia) (Lanphear et al., 2005). Across all previously evaluated studies, associations between blood Pb levels and decrements in full-scale intelligence quotient (FSIQ), infant mental development, memory, learning, and executive function were found in children ages 2 to 17 years with population mean blood Pb levels (measured at various lifestages and time periods) 5-10 µg/dL; however, several results indicated associations in groups of children (ages 2-10 years) with mean blood Pb levels in the lower range of 3-5 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008; Téllez-Rojo, 2008). Based on fewer available studies, the 2006 Pb AQCD described evidence from prospective and cross-sectional epidemiologic studies for associations of childhood blood Pb levels with attention-related behavioral problems in children ages 6-13 years and misconduct and delinquent behavior in children ages 7-17 years and young adults ages 21-22 years (U.S. EPA, 2006b).

Biological plausibility for epidemiologic evidence in children was provided by similarly consistent toxicological findings for Pb-induced impairments in learning and behavior in rodents and monkeys (U.S. EPA, 2006b). Pb exposure was not found consistently to affect the memory of animals. In animals, learning impairments were demonstrated largely as poorer performance in maze tests, shorter interresponse times on schedule controlled behavior tasks, and response perseveration errors in discrimination reversal tests. Some results from these tests also indicated Pb-induced increases in inattention. Pb-induced impulsivity in animals was demonstrated as increased response rates on the Fixed Ratio (FR)/waiting for reward test. These effects on learning and behavioral problems in animals were found predominately with Pb exposures that resulted in blood Pb levels 20-50 µg/dL; however, some studies observed these impairments in rodents (pre- and/or post-natal Pb exposure) and monkeys (postnatal Pb exposure) with blood Pb levels 14-25 µg/dL (Kuhlmann et al., 1997; Altmann et al., 1993; Rice and Karpinski, 1988; Gilbert and Rice, 1987). Toxicological studies further provided biological plausibility for Pb-induced learning impairments and behavioral problems by characterizing modes of action. Evidence for Pb affecting neuronal development and function at the cellular and subcellular level (e.g., blood brain barrier integrity, synaptic architecture during development, neurite outgrowth, glial growth, neurotransmitter release, oxidative stress), provided biological plausibility for associations observed between blood Pb levels and deficits in multiple functional domains such as cognitive function, motor function, memory, mood, and behavioral problems in children. Additional biological plausibility was provided by associations observed of childhood blood Pb levels with changes indicative of neuronal damage and altered brain physiology assessed in small groups of children (Meng et al., 2005; Trope et al., 2001) and young adults (Yuan et al., 2006; Cecil et al., 2005) using magnetic resonance imaging techniques.

A common finding across several different populations of children was a supralinear concentration-response relationship between blood Pb level and cognitive function decrements, i.e., a larger decrement in cognitive function per unit increase in blood Pb level in children in the lower range of the population blood Pb level distribution (Kordas et al., 2006; Schnaas et al., 2006; Téllez-Rojo et al., 2006; Bellinger and Needleman, 2003; Canfield et al., 2003a). Most of these epidemiologic results were based on the analysis of concurrent blood Pb levels and a cut-point of 10 µg/dL to define lower and higher blood Pb levels. These findings were corroborated in pooled analyses of seven cohorts, which indicated that a nonlinear relationship fit the data better than a linear relationship (Lanphear et al., 2005; Rothenberg and Rothenberg, 2005). Explanations for the supralinear concentration-response were not well characterized.

Another area of focus was the comparison of various lifestages and time periods of Pb exposure with respect to increasing risk of neurodevelopmental deficits. Toxicological studies clearly demonstrated that gestational Pb exposure with or without additional early postnatal exposure resulted in neurodevelopmental impairments. Nonetheless, not all neurodevelopmental effects in animals had a single defined window of risk; for example, postnatal-only and lifetime Pb exposures also were shown to impair learning and behavior. Epidemiologic studies observed decrements in cognitive function in children ages 3 to 17 years in association with prenatal, peak childhood, cumulative childhood, and concurrent blood Pb levels. Although examined in few studies, tooth or bone Pb levels were associated with cognitive function decrements and behavioral problems in children and adolescents (Wasserman et al., 2003; Bellinger et al., 1994b; Fergusson et al., 1993; Needleman et al., 1979), also pointing to an effect of cumulative childhood Pb exposure. Among studies of children (ages 3-10 years) that examined blood Pb levels measured at multiple lifestages and time periods, several found that concurrent blood Pb was associated with a similar magnitude or larger decrement in FSIQ than blood Pb levels measured earlier in childhood or averaged over multiple years (Lanphear et al., 2005; Wasserman et al., 1994; Dietrich et al., 1993). A common limitation of prospective studies of children was the high correlation among blood Pb levels at different ages, making it difficult to identify an individual critical lifestage or duration of Pb exposure associated with risk of neurodevelopmental decrements (Lanphear et al., 2005). Some evidence indicated the persistence of neurodevelopmental effects of Pb exposure, by associations of biomarkers of earlier childhood Pb exposure (e.g., deciduous tooth, blood at age 2 or 6 years) with cognitive function decrements and behavioral problems in adolescents and young adults (Ris et al., 2004; Wasserman et al., 2003; Bellinger et al., 1994a; 1994b; Fergusson et al., 1993; Baghurst et al., 1992; Needleman et al., 1979). Persistence of effects also was demonstrated by findings in some studies of rats and monkeys that gestational and/or early postnatal Pb exposures were associated with impairments in cognitive function and behavior in animals evaluated as adults (Kuhlmann et al., 1997; Altmann et al., 1993; Rice, 1992b, 1990).

In epidemiologic studies of adults, a range of nervous system effects (e.g., impaired memory, attention, reaction time, visuomotor tasks and reasoning, alterations in visual or brainstem evoked potentials, postural sway) were mostly clearly indicated in Pb-exposed workers with blood Pb levels in the range of 14 to 40 μg/dL (Iwata et al., 2005; Bleecker et al., 1997; Baker et al., 1979; Cantarow and Trumper, 1944). In the smaller body of studies examining nonoccupationally-exposed adults, poorer cognitive performance was associated with bone Pb levels (Weisskopf et al., 2004; Wright et al., 2003) but not concurrent blood Pb levels (Krieg et al., 2005; Nordberg et al., 2000; Payton et al., 1998; Muldoon et al., 1996). These findings suggested the influence of past or cumulative Pb exposures on cognitive function decrements in nonoccupationally-exposed adults. With

regard to neurodegenerative diseases, whereas a few toxicological studies found Pb-induced amyloid plaques, a pathology commonly found in the brains of adults with Alzheimer's disease (Basha et al., 2005; Zawia and Basha, 2005), epidemiologic studies did not indicate that Pb exposure was associated with Alzheimer's Disease in adults. Blood and bone Pb levels were inconsistently associated with amyotrophic lateral sclerosis (ALS) in adults in the general population; however, in some case-control studies, history of occupational Pb exposure was more prevalent among ALS cases than controls (Kamel et al., 2002; Chancellor et al., 1993). Associations were reported for essential tremor and symptoms of anxiety and depression in adults, but each was examined in only a few studies.

As discussed throughout this section, recent epidemiologic and toxicological studies continued to demonstrate associations of Pb exposure and biomarkers of Pb exposure with nervous system effects. The strongest evidence continued to be derived from associations observed for Pb exposure and blood Pb levels in young animals and children, respectively, with cognitive function decrements. Several recent studies in children expanded the evidence for associations between concurrent blood Pb levels and attention-related behavioral problems. Recent epidemiologic studies in adults focused primarily on cognitive function decrements but provided additional evidence for Pb-associated psychopathological effects, ALS, Parkinson's disease, and essential tremor. Recent toxicological studies supported evidence for the effects of prenatal and postnatal Pb exposure on learning, memory, and impulsivity in animals and examined interactions between Pb exposure and stress. New or expanded areas of toxicological research related to Pb exposure included, neurofibrillary tangle formation and neurodegenerative effects after early life Pb exposures and effects potentially related to psychopathological effects. Recent toxicological studies added to the large extant evidence base for Pb-induced effects on endpoints describing modes of action, including neurotransmitters, synapses, glia, neurite outgrowth, the blood brain barrier, and oxidative stress. The data detailed in the subsequent sections continue to enhance the understanding of the spectrum of nervous system effects associated with Pb exposure.

5.3.2 Cognitive Function

Epidemiologic studies have assessed cognitive function extensively by FSIQ and its verbal and performance subscale components in children ages 3 to 17 years. FSIQ has strong psychometric properties (i.e., reliability, consistency, validity), is among the most rigorously standardized cognitive function measures, is relatively stable in school-age, and has been predictive of life success. In children ages 6 months to 3 years, mental development has been assessed with the Bayley Scales of Infant Development. A large body of evidence also comprises associations of blood and tooth Pb levels with memory and learning, executive function, language, and visuospatial processing. Several of these domains of cognitive function are evaluated in the subtests of FSIQ, and some are more comparable to endpoints examined in tests in animals. Fewer studies have examined academic performance and achievement; however, these outcomes may provide information on the impact of Pb exposure on life success. In the subsequent sections, the epidemiologic evidence for each of these categories of outcomes is reviewed separately in order of strength of evidence as assessed by the following parameters. Emphasis was placed on prospective studies with repeated measurements of blood Pb levels and cognitive function and on studies that examined blood Pb levels more similar to those of contemporary U.S. children (i.e., <5 µg/dL) and children whose blood Pb levels were less influenced by higher past Pb exposures. Studies of chelation in children generally were not included because the high pre-chelation blood Pb levels may limit generalizability of results, and chelation itself has been linked to neurodevelopmental effects.

Many factors have been shown to influence the cognitive function of children, including parental SES, parental education, parental IQ, quality and stability of parental caregiving environment (often measured as Home Observation for the Measurement of Environment inventory [HOME]), nutritional status, and birth weight (Nation and Gleaves, 2001; Wasserman and Factor-Litvak, 2001). These and other influences on neurodevelopment often are correlated with blood Pb levels. Thus, due to their association with both blood Pb level and causal association with outcome, these other risk factors potentially may bias or confound the associations observed between blood Pb level and indices of cognitive function. In the evaluation of the effects of Pb independent from the effects of the other risk factors, greater weight was given to studies that more extensively accounted for potential confounding in the study design or in statistical analyses. A detailed evaluation of control for potential confounding in associations between indicators of Pb exposure and neurodevelopmental effects is located in Section 5.3.14.

5.3.2.1 Full Scale IQ in Children

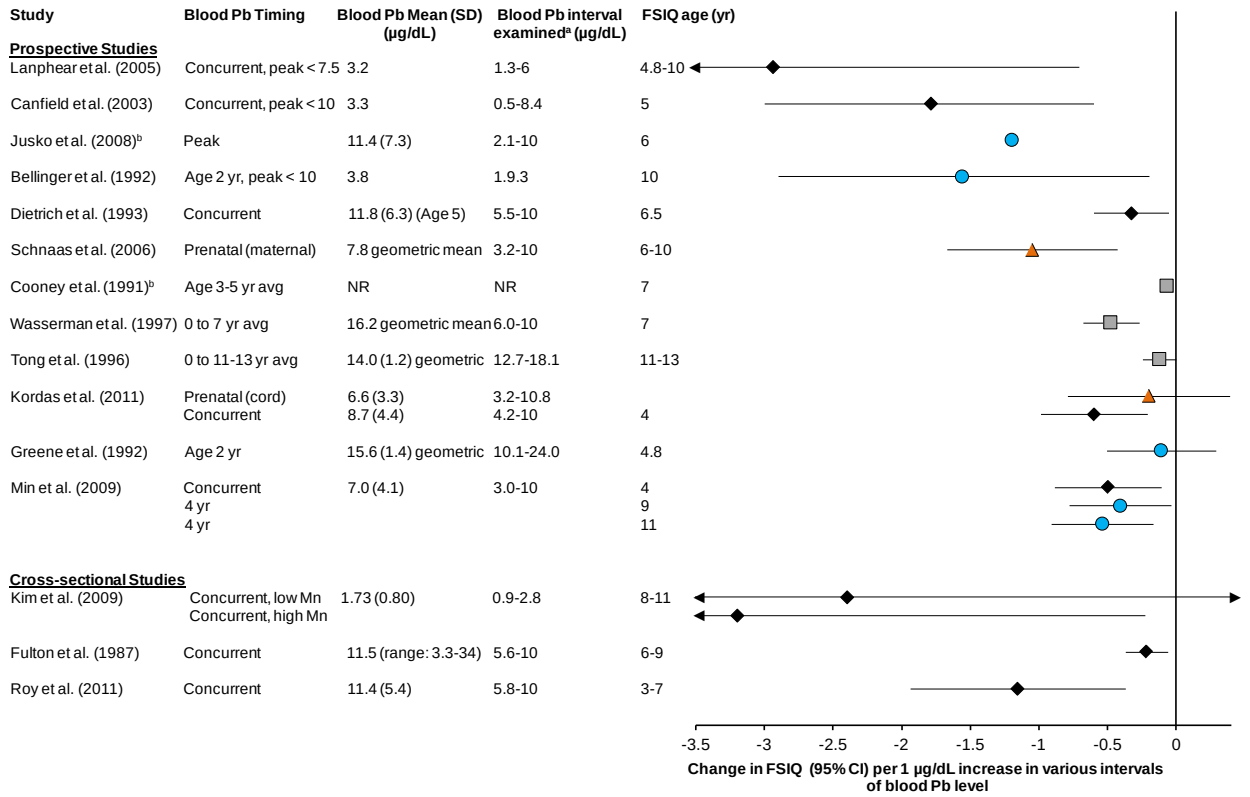
Evidence from Prospective Studies

Prospective cohort studies that were initiated in the 1980s addressed some limitations of cross-sectional studies, including better characterizing the temporal sequence between blood Pb levels and cognitive function, examining the persistence of cognitive function decrements to older ages, and comparing associations among blood Pb levels measured at various lifestages or representing various time periods. Recruitment of participants before or at birth without consideration of Pb exposure or maternal IQ, high follow-up participation (>70%), and nonselective loss-to-follow-up in most studies increase confidence that the observed associations are not due to selection bias. Moreover, cooperation among investigators to adopt similar study protocols (e.g., similar tests of IQ and consideration of similar potential confounding factors) strengthened inferences regarding the consistency of associations with blood Pb level by facilitating pooled analyses and by reducing sources of heterogeneity in evaluating results across populations that varied in geographic location, proximity to Pb sources, blood Pb level range, race/ethnicity, and SES.

Individual cohort studies of varying sample sizes (n = 148-375) conducted in several different populations (e.g., Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie and Sydney, Australia; and Kosovo, Yugoslavia) were consistent in demonstrating associations of higher blood Pb measured prenatally (maternal or umbilical cord), earlier in childhood, or averaged over childhood with lower FSIQ measured later in childhood, i.e., 4 to 17 years (Schnaas et al., 2006; Ris et al., 2004; Canfield et al., 2003a; Schnaas et al., 2000; Factor-Litvak et al., 1999; Tong et al., 1996; Wasserman et al., 1994; Dietrich et al., 1993b; Baghurst et al., 1992; Bellinger et al., 1992; Bellinger et al., 1991; McMichael et al., 1988) (Figure 5-2 and Table 5-3). Null or weak associations were limited to a few cohorts, namely, the Cleveland and Sydney cohorts (Greene et al., 1992; Cooney et al., 1991; 1989a, b; Ernhart et al., 1988). In the prospective studies, lower FSIQ also was associated with higher concurrent blood Pb levels (Figure 5-2 and Table 5-3) and tooth Pb levels. These latter results were based on cross-sectional analyses; however, the pattern of associations observed for blood Pb levels measured at various lifestages or time periods does not indicate that reverse causation explains the FSIQ decrements observed in association with concurrent blood Pb or tooth Pb levels.

In addition to better characterizing the temporal sequence between Pb exposure and decrements in FSIQ, a common strength of most prospective studies was the adjustment for several of the potential confounding factors noted above, including maternal IQ and

education, child sex and birth weight, SES, and HOME score (Table 5-3). Although not considered as frequently, some studies also indicated lack of confounding by parental smoking, birth order, and nutritional factors. Multiple testing of associations with blood Pb levels and/or FSIQ was common in prospective studies that found and did not find associations between blood Pb level and FSIQ. However, higher probability of associations due to chance alone does not appear to unduly influence the evidence because in studies that found associations, there was a consistent pattern of blood Pb-associated cognitive function decrements across the various ages of blood Pb level and/or cognitive assessments evaluated (Table 5-3). Studies finding null or weak associations also tended to show a consistent pattern across the various analyses conducted.



[a]See Table 5-3 for explanation of the blood Pb level interval examined. Where possible, effect estimates were calculated for the lowest range examined or the 10th percentile of blood Pb level to a blood Pb level of 10 µg/dL.
[b]Sufficient data were not provided to calculate 95% CI.
Note: Results are presented for most of the cohorts examined in the literature and generally are presented in order of strength of study design and representativeness of study population. Evidence usually is presented for the oldest age examined in cohorts. Multiple results from a cohort are grouped together. To facilitate comparisons among effect estimates across studies with different distributions of blood Pb levels and model structures (e.g., linear, log-linear), effect estimates are standardized to a 1 µg/dL increase for the lowest range of blood Pb levels examined or the interval from the 10th percentile of blood Pb level to 10 µg/dL. For populations with 10th percentile near or above 10 µg/dL, the effect estimate was calculated for the 10th to 90th percentile of blood Pb level. The percentiles are estimated using various methods and are only approximate values. Effect estimates are assumed to be linear within the blood Pb level interval evaluated. The various tests used to measure FSIQ are scored on a similar scale (approximately 40-160 FSIQ points). Black diamonds, blue circles, orange triangles, and gray squares represent effect estimates for concurrent, earlier childhood, prenatal, and lifetime average blood Pb levels, respectively. The lines represent 95% confidence intervals (CI).

Study	Study Population and Methodological Details	Blood Pb Data (µg/dL)	FSIQ Testing[a]	Effect Estimate (95% CI)[b]
Prospective Studies:				
Lanphear et al. (2005)	103 children pooled from Boston, Cincinnati, Cleveland, Mexico City, Port Pirie, Rochester, and Yugoslavia cohorts. Uniform analysis of cohorts from diverse locations and SES. Blood Pb levels and FSIQ measured at different ages. Several sensitivity analyses to examine heterogeneity of results by cohort, model specification, and confounding. Linear regression model adjusted for HOME score, birth weight, maternal IQ, maternal education. Also considered potential confounding by child sex, birth order, maternal age, marital status, prenatal smoking status and alcohol use.	Concurrent, children with peak <7.5 Mean: 3.2 Interval analyzed: 1.3-6.0 = 5th-95th percentiles	WISC-III, WISC-R, WPPSI, WISC-S Ages 4.8-10 yr	-2.94 (-5.16, -0.71)
Canfield et al. (2003a)	101 children born 1994-1995 followed from age 6 mo to 5 yr, Rochester, NY Recruitment from study of dust control. 73% nonwhite. High follow-up participation, no selective attrition. Linear regression model adjusted for maternal race, IQ, education, and prenatal smoking status, household income, HOME score, child sex, Fe status, birth weight.	Concurrent, children with peak <10 Mean: 3.3 Interval analyzed: <1-8.4 = range (1 = detection limit)	Stanford-Binet Age 5 yr	-1.8 (-3.0, -0.60)
Jusko et al. (2008)	174 children born 1994-1995 followed from age 6 mo to 6 yr, Rochester, NY Same cohort as above. High follow-up participation. Participants had higher maternal IQ. Nonparametric regression model adjusted for maternal race, IQ, education, and prenatal smoking status, HOME score, family income, child sex, birth weight, and Fe status.	Peak Mean (SD): 11.4 (7.3) Interval analyzed: 2.1-10	WPPSI-R Age 6 yr	-1.2[c]
Bellinger and Needleman (2003)	48 children followed from birth (1979-1981) to age 10 yr, Boston, MA area Recruitment at birth hospital. Moderate follow-up participation. Participants had higher SES and HOME scores. 95% white. Linear regression model adjusted for HOME score (age 10 and 5 yr), maternal race, IQ, and marital status, SES, child sex, birth order, and stress, and number of residence changes. Also considered potential confounding by family stress, maternal age, psychiatric factors, child serum ferritin levels.	Earlier childhood (age 2 yr), children with peak <10 Mean: 3.8 Interval analyzed: 1-9.3 = range	WISC-R Age 10 yr	-1.56 (-2.9, -0.20)
Mazumdar et al. (2011)	43 adults followed from birth (1979-1981) to age 28-30 yr, Boston, MA area Same cohort as above. Small proportion of original cohort but no selective attrition. 93% white. Linear regression model adjusted for maternal IQ. Also found associations adjusted for maternal marital status at birth, education at birth, prenatal smoking status, or alcohol use, HOME score (mean across ages), subject sex, birth weight, birth order, gestational age, race, concussion history, or current smoking status. Also considered potential confounding by subject alcohol use.	Earlier childhood avg (age 6 mo-10 yr): NR Mean (SD), [age]: 8.0 (5.3) [6 mo], 10.0 (6.7) [1 yr], 7.7 (4.0) [2 yr], 6.7 (3.6) [4 yr], 3.0 (2.7) [10 yr].	WAIS Age 28-30 yr	-1.1 (-2.29, 0.06)[d]

Dietrich et al. (1993b)	253 children followed from birth (1979-1985) to age 6.5 yr, Cincinnati, OH Recruitment at prenatal clinic. High follow-up participation. Participants had slightly higher age 1 yr blood Pb levels. Primarily African-American. Linear regression model adjusted for HOME score, maternal IQ and prenatal cigarette smoking, child birth weight, birth length, and sex. Also considered potential confounding by perinatal complications, prenatal maternal substance abuse, nutritional status.	Concurrent NR Age 5 yr Mean (SD): 11.8 (6.3) Interval analyzed: 5.5 (10th percentile)-10	WISC-R Age 6.5 yr	-0.33 (-0.60, -0.06)
Schnaas et al. (2006)	150 children followed from birth (1987-1992) to age 10 yr, Mexico City, Mexico. Recruitment at prenatal clinic. Low follow-up participation. Participants had higher SES, FSIQ, higher blood Pb level before age 5 yr, lower at older ages. Log linear mixed effects model adjusted for SES, maternal IQ, HOME score, child sex, birth weight, and postnatal blood Pb, indicator of first FSIQ, random slope for subject. Most covariates assessed in pregnancy or within age 6 mo.	Prenatal (maternal 28-36 weeks) Geometric mean (5th-95th): 7.8 (2.5-24.5) Interval analyzed: 3.2 (10th percentile)-10	McCarthy GCI Ages 6-10 yr	-1.05 (-1.67, -0.43)
Cooney et al. (1991)	175 children followed from birth (1983) to age 7 yr, Sydney, Australia Recruitment at birth hospital. Moderate follow-up participation but no selective attrition. 100% white. Linear regression adjusted for maternal education and IQ, paternal education and occupation, HOME score, child gestational age.	Age 3-5 yr avg: NR Age 5 yr Mean (Max): 8.3 (27)	WISC-R Age 7 yr	-0.07[c]
Wasserman et al. (1997)	258 children followed prenatally (1984-1985) to age 7 yr, Kosovo, Yugoslavia 50% subjects live near Pb sources. Low follow-up participation. Participants had lower HOME score, maternal IQ, higher early childhood blood Pb levels and fewer subjects lived in town with Pb sources. Generalized estimating equations with log blood Pb adjusted for maternal age, education, and IQ, child age, sex, sibship size, and birth weight, language spoken in home, HOME score.	Lifetime avg (to age 7 yr) Geometric mean: 16.2 Interval analyzed: 6.0 (10th percentile)-10	WISC-III Age 7 yr	-0.48 (-0.68, -0.27)
Tong et al. (1996)	375 children followed from birth (1979-1982) to age 11-13 yr, Port Pirie, Australia Residence near Pb smelter. Moderate follow-up participation. Participants had higher parental occupational prestige. Regression model adjusted for maternal IQ and age, parental occupational prestige, smoking, marital status, and education, HOME score, family functioning score, family size, child sex, age, school grade, birth weight, birth order, feeding method, breastfeeding duration, life events, prolonged absences from school. Also considered potential confounding by maternal psychopathology, child Fe status, medication use in previous 2 weeks, length of residence in area.	Lifetime avg (to age 11-13 yr) Geometric mean (GSD): 14.0 (1.2) Interval analyzed: 12.7-18.1 = 10th-90th percentiles	WISC-R Age 11-13 yr	-0.12 (-0.24, -0.003)
Kordas et al. (2011)	186 children followed from birth (1994-1995) to age 4 yr, Mexico City, Mexico Recruitment at prenatal clinic. Low follow-up participation but no selective attrition. Linear regression model adjusted for maternal age, education, IQ, smoking status, and marital status, crowding in home, type of floor in home, child sex, birth weight, gestational age. Did not consider potential confounding by parental caregiving quality.	Prenatal (cord) mean (SD): 6.6 (3.3), Interval analyzed: 3.2-10.8 = 10th-90th percentiles	Prenatal	-0.20 (-0.79, 0.39)
		Concurrent mean (SD): 8.7 (4.4) , Interval analyzed: 4.2 (10th percentile)-10	Concurrent McCarthy GCI Age 4 yr	-0.60 (-0.99, -0.21)

Log linear regression model adjusted for SES, maternal education and vocabulary score, # children <18 yr, HOME score, parity, family environment scale, child sex. Also considered potential confounding by prenatal alcohol, marijuana, smoking, or cocaine use, crowding, child age and life stress, caregiver life stress, conflict tactics.	Concurrent Mean (SD): 5.4 (3.3) Interval analyzed: 2.3-9.5 = 10th-90th percentiles	WISC-III Age 7.5 yr	-0.22 (-0.38, -0.05)[e,f] Standardized regression coefficient

[a]WISC = Wechsler Intelligence Scale for Children, WPPSI = Wechsler Preschool and Primary Scale of Intelligence, WAIS = Wechsler Adult Intelligence Scale, GCI = General Cognitive Index, BASC = British Ability Scales Combined, KEDI = Korean Educational Development Institute

[b]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the lowest range examined in study or 10th percentile to 10 µg/dL. For populations with 10th percentiles near or above 10 µg/dL, effect estimates were calculated for the 10th-90th percentile interval of blood Pb level. Effect estimates are assumed to be linear within the evaluated interval of blood Pb level. The percentiles are estimated using various methods and are only approximate values.

[c]Sufficient data were not provided to calculate 95% CI.

[d]Results not included in Figure 5-2 because FSIQ assessed in adults.

[e]Results not included in Figure 5-2 because blood Pb level analyzed as categorical variable or because standardized regression coefficient reported.

[f]95% CIs were constructed using a standard error that was estimated for the reported p-value of 0.01.

Across the cohort studies, blood Pb-associated FSIQ decrements were found in populations with mean blood Pb levels 5-10 µg/dL. In analyses restricted to children in the lower range of the blood Pb distribution (e.g., peak <10 µg/dL), associations were observed in groups of children with mean blood Pb levels 3-4 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008). The analysis of the Rochester cohort is particularly informative for lower blood Pb levels of children (mean at age 5 years: 5.8 µg/dL) compared to other cohorts and the greater consideration for potential confounding by factors such as sex, race, family income, maternal education, race, prenatal maternal smoking, birth weight, maternal IQ, HOME score, and transferrin saturation which indicates iron status and for providing unadjusted and covariate-adjusted results (Canfield et al., 2003a). At age 5 years, higher age 6-24 month average, peak, concurrent, and lifetime average blood Pb levels (area under the curve calculation using repeat measurements between age 6 months and 5 years) were associated with lower FSIQ, and while effect estimates in the covariate-adjusted model were 40-45% smaller than estimated in the unadjusted models, they remained statistically significant. A larger effect was estimated for the 101 (59%) children whose peak blood Pb levels never exceeded

10 µg/dL, i.e., -1.8 points (95% CI: -3.0, -0.60) per 1 µg/dL in concurrent blood Pb level. Similarly, Bellinger and Needleman (2003) estimated a larger effect in the subset of the Boston cohort (n = 48, 32%) with peak blood Pb levels <10 µg/dL, i.e., -1.6 points (95% CI: -2.9, -0.2) per 1 µg/dL increase in age 2-year blood Pb level. The mean blood Pb levels in these subsets of children were 3.3 (Rochester) and 3.8 µg/dL (Boston) closer to that of current U.S. children compared with other prospective studies.

Analyses of the Cincinnati and Port Pirie, Australia cohort also indicated associations between blood Pb level and FSIQ decrements with as extensive consideration for potential confounding (Table 5-3) albeit in populations with higher blood Pb levels (i.e., mean at age 5 years: 11.8 µg/dL, lifetime average geometric mean: 14.0 µg/dL) (Tong et al., 1996; Dietrich et al., 1993b). In contrast with other studies, in the Cleveland cohort, associations of blood Pb level (ages 2 and 3 years) and tooth Pb level with FSIQ (ages 3 and 4.8 years), became attenuated or were too imprecise to be informative with adjustment for a large number of potential confounding factors, including maternal substance abuse, home cleanliness, and pica behavior, which were not considered widely in other studies (Greene et al., 1992; Ernhart et al., 1988). HOME score accounted for a large proportion of the variance in FSIQ and was the major factor accounting for the attenuation of the effect estimates for Pb biomarkers. The association between tooth Pb level and FSIQ at age 4.8 years was attenuated with additional adjustment for HOME score but was estimated with similar precision (-3.0 points [95% CI: -6.4, 0.32] per 1 µg/g increase in tooth Pb level) (Greene and Ernhart, 1993). The few weak or null associations do not mitigate the otherwise strong evidence provided by other studies. The Cleveland (Greene et al., 1992) and Sydney (Cooney et al., 1991) studies were not outliers with respect to population mean blood Pb levels or the specific confounding factors considered (Table 5-3), and the Cleveland cohort had high prevalence of maternal prenatal substance abuse which may limit the representativeness of results. Further, the blood Pb-FSIQ association in children was substantiated in a pooled analysis of seven prospective studies by Lanphear et al. (2005), which included the Cleveland cohort, as well as multiple meta-analyses that combined results across various prospective and cross-sectional studies, including those from the Cleveland and Sydney cohorts (Pocock et al., 1994; Schwartz, 1994; Needleman and Gatsonis, 1990). The meta-analysis by Schwartz (1994) demonstrated the robustness of evidence to potential publication bias. The addition of eight hypothetical studies with a zero effect and with the average weight of the eight published studies resulted in a 50% lower but still negative and precise ($p < 0.001$) blood Pb-FSIQ effect estimate.

The pooled analysis of seven prospective studies included individual-level data from 1,333 children ages 4.8-10 years of age with a median (5th-95th percentile) concurrent blood Pb level of 9.7 µg/dL (2.5-33.2 µg/dL) (Lanphear et al., 2005). In multivariate

models that adjusted for study site, maternal IQ, HOME score, birth weight, and maternal education, higher concurrent, peak, lifetime average, and early childhood blood Pb levels were associated with lower FSIQ measured at age 4.8-10 years. Various models were investigated to characterize the shape of the blood Pb-FSIQ concentration-response relationship. Consistent with the supralinear concentration-response relationship found in several individual cohort studies, Lanphear et al. (2005) found that a nonlinear (i.e., log-linear) model fit the data better than a linear model. The nonlinear relationship was indicated further by observations of a greater decrease in FSIQ for a 1 µg/dL increase in concurrent blood Pb for the 244 (18%) children who had peak blood Pb levels <10 µg/dL (-0.80 points [95% CI: -1.74, -0.14]) and the 103 (8%) children with peak blood Pb levels <7.5 µg/dL (-2.9 points [95% CI: -5.2, -0.71]). Among children with peak blood Pb <10 µg/dL and <7.5 µg/dL, the median concurrent blood Pb levels were 4.2 µg/dL and 3.2 µg/dL, respectively (Hornung, 2008).

An additional strength of the pooled analysis by Lanphear et al. (2005) was the examination of several potential confounding factors related to SES and the caregiving environment. Variables such as HOME score, birth weight, maternal IQ, and maternal education were selected for inclusion in the final model with blood Pb level based on their statistically significant association with FSIQ. Child sex, maternal prenatal tobacco or alcohol use, maternal age at delivery, marital status, and birth order were not statistically significantly associated with FSIQ and did not alter the effect estimate for concurrent blood Pb level adjusted for the four aforementioned covariates. While a smaller decrement in FSIQ was estimated for concurrent blood Pb level in the adjusted model than in the unadjusted model (-4.7 points [95% CI: -5.7, -3.6] versus -2.7 points [95% CI: -3.7, -1.7] per log increase in concurrent blood Pb level), the adjusted blood Pb level effect estimate did not lose precision.

The few prospective studies published since the 2006 Pb AQCD continued to demonstrate associations between higher blood Pb level and lower FSIQ, in some cases, with additional follow-up of previous cohorts. Similar to studies reviewed in the 2006 Pb AQCD, most recent studies demonstrated associations between blood Pb level and lower FSIQ in populations with mean blood Pb level between 5 to 10 µg/dL. Jusko et al. (2008) affirmed the findings in the Rochester cohort previously reported by Canfield et al. (2003a), who examined the cohort at age 5 years. Jusko et al. (2008) examined 174 Rochester cohort subjects at age 6 years and similar to Canfield et al. (2003a), found that an increase in peak blood Pb level was associated with a larger decrease in FSIQ among children with peak blood Pb levels <10 µg/dL than among children with peak blood Pb levels 10-20 µg/dL (-1.2 points versus -0.32 points per 1 µg/dL increase in blood). The age 6 year analysis had similarly extensive consideration for potential confounding as did

Canfield et al. (2003a) (Table 5-3) and also indicated associations with higher concurrent, infancy average, and lifetime average blood Pb levels (effect estimates not reported).

Additional evidence was provided for children in Mexico City, albeit in a separate cohort of children born later with lower blood Pb levels at corresponding ages. Among 150 children born 1987-1992, Schnaas et al. (2006) previously reported larger Pb-associated decrements in FSIQ for prenatal maternal (28-36 weeks) blood Pb levels than for child concurrent blood Pb levels between ages 1 and 10 years. In contrast, Kordas et al. (2011) found that an increase in concurrent blood Pb level was associated with a larger decrement in FSIQ at age 4 years than was an increase in cord blood Pb level with adjustment for several potential confounding factors (HOME score not examined) (Table 5-3). The 186 children in the latter study were born 1994-1995 and at age 4 years had a mean blood Pb level of 8.7 µg/dL. In Schnaas et al. (2006), the geometric mean blood Pb level at age 4 years was 10.3 µg/dL. It is not clear whether different temporal patterns of Pb exposure or age of FSIQ assessment may have contributed to the contrasting associations for prenatal and concurrent blood Pb levels in these two Mexico City cohorts.

Mazumdar et al. (2011) followed the Boston cohort (Bellinger et al., 1992) to age 28-30 years, and indicated that the effect of childhood Pb exposures may persist to adulthood. Only 43 of the original 249 subjects enrolled at birth were examined at age 28-30 years, but they did not differ from the original cohort in demographic characteristics or blood Pb history. Higher blood Pb levels measured at age 6 months, 4 years, 10 years, and averaged over childhood (to age 10 years) (means: 3 µg/dL at age 10 years to 8 µg/dL at age 6 months) were associated with lower FSIQ in adults with adjustment for sex, birth weight, birth order, gestational age, maternal marital status, maternal education, maternal IQ, race, maternal smoking and alcohol use in pregnancy, average of childhood HOME score, concussion, and subject current smoking status. The effect estimates were similar in magnitude for all childhood blood Pb measures, except for age 6 month blood Pb level, which was associated with a smaller FSIQ decrement.

Min et al. (2009) found higher earlier childhood blood Pb levels (age 4 year) to be associated with decrements in FSIQ in another cohort of children in Cleveland, OH between ages 4 and 11 years, indicating persistence of effects (Figure 5-2 and Table 5-3). However, similar to the other Cleveland cohort (Greene et al., 1992), the recent cohort had high prevalence of prenatal alcohol and drug exposure. These exposures were weakly associated with FSIQ or did not influence the blood Pb-FSIQ association, indicating lack of strong confounding bias. However, because the population lacks representativeness, these findings are less of a consideration in drawing conclusions regarding the effects of Pb exposure on FSIQ of children.

An important consideration in the evaluation of epidemiologic evidence is the precision of effect estimates, both within and among studies. There was variability in precision among studies, which appeared to be influenced by sample size rather than the age of subjects or the extent of adjustment for potential confounding factors. Analyses of the Port Pirie (n = 375, ages 11-13 years) and Yugoslavia (n = 258, age 7 years) cohorts (Wasserman et al., 1997; Tong et al., 1996) and the pooled analysis of 1,333 children (Lanphear et al., 2005) estimated more precise effects compared to the Boston (n = 148, age 10 years) and Rochester cohorts (n = 172, age 5 years) (Canfield et al., 2003a; Bellinger et al., 1992). Analyses of the Yugoslavia and Port Pirie cohorts did not necessarily have more or less extensive adjustment for potential confounding.

Among prospective studies, a wide range of blood Pb-associated FSIQ decrements was estimated (Figure 5-2 and Table 5-3). This wide range is not unexpected, given differences among studies in blood Pb level ranges, model specification (linear versus log linear), lifestage or time period of blood Pb level examined, and distribution of potential confounding factors. The pooled analysis examined study populations of diverse SES, maternal education, and cultural backgrounds with the same model and indicated precision of effect (Lanphear et al., 2005). A series of sensitivity analyses, in which one cohort was excluded at a time, revealed that no single study was responsible for the results. Per log increase in blood Pb level, effect estimates excluding one study at a time fell within a narrow range, -2.36 to -2.94 (blood Pb level ranges for sensitivity analyses not reported). Precision of effect also was indicated by the similar effect estimates found with similar model specifications, population blood Pb levels, and sample sizes in the Boston and Rochester cohorts (Table 5-3), but very different SES and racial distributions of the cohorts, and different ages of blood Pb level and FSIQ examined (Canfield et al., 2003a; Bellinger et al., 1992). These estimates were larger than those found in the Cincinnati, Port Pirie, and Yugoslavia cohorts but were based on similar extent of adjustment for potential confounding factors. Several of the smaller blood Pb-associated FSIQ decrements were based on log-linear models that estimated effects at higher blood Pb levels (10th percentiles >5.5 versus 2 µg/dL). The widely different null associations found in the Cleveland cohort have weaker implications because of the nonrepresentativeness of the cohort due to their high prevalence of prenatal alcohol and drug exposure (Greene et al., 1992; Ernhart et al., 1988).

Evidence from Cross-sectional Studies

The smaller body of cross-sectional studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) found associations of higher concurrent blood (Fulton et al., 1987) or tooth (Needleman et al., 1979) Pb levels with FSIQ decrements in children ages 6-9 years, and associations also were found in the few recent studies in children ages 3-11 years (Figure 5-2 and Table 5-3). Several cross-sectional studies had larger sample sizes (n = 279-717) than the prospective studies and produced effect estimates with similar precision. Previous meta-analyses produced similar combined blood Pb-FSIQ effect estimates for prospective and cross-sectional studies (Pocock et al., 1994; Schwartz, 1994). However, in this ISA, the cross-sectional findings were given less weight in conclusions regarding Pb-associated effects on cognitive function. The temporal sequence between Pb exposure and decreases in FSIQ is difficult to establish. Some studies had population-based recruitment, high participation rates, and did not indicate undue selection bias, but the evidence overall had less consideration for potential confounding by parental caregiving quality and/or parental IQ (Roy et al., 2011; Kim et al., 2009b; Zailina et al., 2008; Surkan et al., 2007; Needleman et al., 1979). The meta-analysis by Pocock et al. (1994) noted the lack of adequate control for potential confounding factors in previous cross-sectional studies. Other cross-sectional studies lacked representative study populations because of high prevalence of prenatal alcohol (Chiodo et al., 2004) or drug exposure (Chiodo et al., 2007).

Among the cross-sectional studies, Fulton et al. (1987) had more extensive consideration for potential confounding. Among 501 children, ages 6-9 years, in Edinburgh, Scotland, a 1 µg/dL increase in concurrent blood Pb level in the interval between 5.6 and 10 µg/dL was associated with a 0.22-point decrease (-0.37, -0.06) in FSIQ, after adjustment for several factors related to SES, parental health and mental health, child health, and parental caregiving quality (Table 5-3). The effect estimate from this study was among the smallest produced by cross-sectional studies. The study population was representative of the source population but had much higher blood Pb levels (geometric mean: 11.4 µg/dL) than those of most of the current U.S. population of children.

Recent cross-sectional studies examined potential confounding by parental IQ and education and SES but not parental caregiving quality. Studies that examined populations with mean concurrent blood Pb levels <4 µg/dL did not conclusively indicate associations with FSIQ decrements at lower blood Pb levels. Among 389 children from urban Boston, Massachusetts and rural Farmington, Maine with mean concurrent blood Pb level 2.2 µg/dL, lower FSIQ was limited to children with blood Pb levels 5-10 µg/dL, with children with blood Pb levels 1-2 µg/dL serving as the referent group (Table 5-3) (Surkan et al., 2007). There was consideration for potential confounding by several factors, including age, race/ethnicity, birth weight, SES, primary caregiver IQ, SES,

education and marital status, parenting stress, and maternal utilization of prenatal or annual health care. Other recent cross-sectional studies found associations at lower concurrent blood Pb levels; however, some of the children likely had higher earlier childhood Pb exposures, which may have contributed to the associations observed with relatively low concurrent blood Pb levels. In a group of 279 children ages 8-11 years from four Korean cities with a mean concurrent blood Pb level 1.73 µg/dL, Kim et al. (2009b) found an association between higher concurrent blood Pb level and lower FSIQ with adjustment for parental education, yearly income, prenatal and postnatal smoking exposure, birth weight, age, and sex. The adjusted effect estimate was attenuated but similarly precise as the unadjusted estimate. The concurrent blood Pb-FSIQ and verbal IQ relationship was modified by concurrent blood manganese (Mn) levels. Blood Pb and Mn levels were not correlated ($r = 0.03$, $p = 0.64$). Higher concurrent blood Pb level was associated with lower FSIQ in both children in high Mn (above the median of 1.4 µg/dL) and low Mn group (below the median of 1.4 µg/dL) but a larger FSIQ decrement in the 130 children in the high Mn group (-3.2 points [95% CI: -6.1, -0.23] per 1 µg/dL increase in the 10th to 90th percentile interval 0.9-2.8 µg/dL) compared with children in the low Mn group (-2.4 points [95% CI: -6.0, 1.1]). The biological plausibility for the Pb-Mn interaction is provided by observations that Mn has similar modes of action and cellular targets as does Pb, i.e., altering Ca^{2+} metabolism, inducing oxidative damage in neuronal cells, diminishing dopamine transmission. Among 169 children in Malaysia, ages 6-8 years, concurrent blood Pb (mean ~4 µg/dL) level but not parental education or family income was associated with FSIQ decrements, producing uncertainty as to whether these potential confounding factors were measured adequately (Zailina et al., 2008).

Other recent cross-sectional studies found associations in populations of children with relatively higher concurrent blood Pb levels (means >8 µg/dL). Evidence demonstrates that Pb affects dopaminergic neurons and dopamine release (Section 5.3.11.8). Further, dopaminergic activity is a key mediator of cognitive function. These findings suggest that variants in dopamine-related genes may modify Pb-associated effects on cognition. Epidemiologic evidence for effect modification is not consistent; however, subgroup analyses are subject to higher probability of findings by chance. The larger of these studies (n = 717 children ages 3-7 years in Chennai, India) with higher concurrent blood Pb levels (mean: 11.4 µg/dL) found that a 1 µg/dL higher blood Pb level was associated with a larger decrease in FSIQ among the 72 children with the Taq A1/A1 dopamine receptor (DRD2) variant (-2.5 points [95% CI: -5.0, -0.04] within the blood Pb level interval 5.8-10 µg/dL) than among the 651 children with the Taq A2/A2 variant (-1.1 points [-2.3, -0.12]) (Roy et al., 2011). Kordas et al. (2011) did not find effect modification in a smaller study of 186 children in Mexico City with a mean concurrent blood Pb level of 8.7 µg/dL. Another difference between studies that may have contributed to the difference in effect modification by the DRD2 variant was an

association observed between Taq A1/A1 genotype and higher mean FSIQ score in the group in Mexico but no association in the group in India.

In summary, a majority of prospective and cross-sectional studies demonstrated associations between higher blood Pb level and lower FSIQ in children ages 3-17 years (e.g., Figure 5-2 and Table 5-3). While studies performed numerous tests, bias due to increased probability of findings by chance was unlikely because most studies found a consistent pattern of association across the ages of blood Pb level and FSIQ analyzed. Across studies, FSIQ was measured with similar instruments scored on similar scales with similar measurement error. The key supporting evidence is provided by the prospective studies, which better indicated the temporal sequence between blood Pb levels measured earlier in childhood or averaged over multiple years or tooth Pb levels and FSIQ measured later in childhood. Prospective studies also had more extensive consideration for potential confounding by maternal IQ and education, SES, birth weight, smoking exposure, parental caregiving quality, and in a few cases, other birth outcomes and nutritional factors. Further, the representativeness of findings was supported by associations found in diverse populations (e.g., Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie and Sydney, Australia; and Kosovo, Yugoslavia) and in studies examining populations recruited from prenatal clinics, hospital maternity departments, or schools with high follow-up participation and lack of biased follow-up participation by blood Pb level and FSIQ. The few weak or null associations found in Cleveland and Sydney cohorts were adjusted for similar potential confounding factors and thus do not mitigate the otherwise strong evidence. The blood Pb-FSIQ association in children was substantiated in a pooled analysis of seven prospective studies by Lanphear et al. (2005) as well as multiple meta-analyses that combined results across various prospective and cross-sectional studies (Pocock et al., 1994; Schwartz, 1994; Needleman and Gatsonis, 1990), with Schwartz (1994) demonstrating the robustness of evidence to potential publication bias.

Across the prospective studies, blood Pb-associated FSIQ decrements were found with concurrent, prenatal (maternal or cord), earlier childhood, multiple year average, or lifetime average blood Pb levels. Associations also were found with tooth Pb levels. There is no clear indication of a stronger association of FSIQ with blood Pb level measured at a particular lifestage or time period. Concurrent blood Pb level in children reflects recent and past Pb exposures. Thus, several observations point to an effect of cumulative childhood Pb exposure. Blood Pb-associated FSIQ decrements were found in populations with mean blood Pb levels 5-10 µg/dL. A common finding was a supralinear concentration-response relationship, i.e., a larger decrement in cognitive function per unit increase in blood Pb level in children in the lower range of the population blood Pb level distribution. In analyses restricted to children in the lower range of blood Pb levels

(e.g., peak <10 µg/dL), associations were found in groups of children with mean blood Pb levels 3-4 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008). Precision of effect estimates was demonstrated in the pooled analysis by the narrow range of estimates, -2.36 to -2.94 points per log increase in blood Pb level, obtained by excluding one study at a time (Lanphear et al., 2005). Across individual studies, there was a wide range of effect estimates reported for blood Pb-associated FSIQ decrements. However, there was variability in model specification and blood Pb level ranges examined among studies (Figure 5-2 and Table 5-3). Similarly larger effect estimates were found in the Boston and Rochester cohorts, which differed in racial and SES distributions. Although these studies had smaller sample sizes, they had at least as extensive consideration for potential confounding as other studies (Canfield et al., 2003a; Bellinger et al., 1992). Each study estimated larger effects for children whose peak blood Pb levels never exceeded 10 µg/dL, -1.8 points (95% CI: -3.0, -0.60) per 1 µg/dL increase in concurrent blood Pb level in the Rochester cohort (Canfield et al., 2003a) and -1.6 points (95% CI: -2.9, -0.2) per 1 µg/dL increase in age 2-year blood Pb level in the Boston cohort (Bellinger and Needleman, 2003). These subsets of children had mean blood Pb levels of 3.3 (Rochester) and 3.8 µg/dL (Boston), lower than those examined in other prospective studies.

5.3.2.2 Bayley Scales of Infant Development

The Mental Development Index (MDI) of the Bayley Scales of Infant Development is a widely used test of infant mental development. Black et al. [(2004) and Pollit (2005)] asserted that the MDI is a reliable indicator of current development and cognitive functioning of the infant, integrating cognitive skills such as sensory/perceptual acuities, discriminations, and response; acquisition of object constancy; memory learning and problem solving; vocalization and beginning of verbal communication; and basis of abstract thinking. However, the MDI test is not an intelligence test, and MDI scores, particularly before ages 2-3 years, are not necessarily correlated with later measurements of FSIQ in children with normal development. In the review of the MDI evidence, emphasis was placed on examinations at ages 2-3 years, which have test items more similar to those in school-age IQ tests. Most of the prospective studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) found associations of prenatal, earlier infancy, and concurrent blood Pb level with MDI score in children between ages 2 and 3 years, and recent studies examined and found associations with cord blood Pb level (Table 5-4).

The prospective studies found blood Pb-associated decrements in MDI in some large (n = 146-592) populations with mean blood Pb levels 5-10 µg/dL. Recruitment of participants before or at birth without consideration of Pb exposure or maternal IQ, high to moderate follow-up participation, and nonselective loss-to-follow-up in most studies increase confidence that the observed associations are not due to selection bias. Comparisons of blood Pb levels measured at various lifestages did not clearly indicate a stronger effect on MDI of prenatal or postnatal childhood blood Pb levels. While the prospective studies adjusted for birth outcomes and maternal IQ and education, most did not adjust for other SES indicators or parental caregiving quality. Concurrent and cord blood Pb levels were associated with MDI, with additional adjustment for SES and HOME score in the Boston cohort and HOME score in the Yugoslavia cohort (Wasserman et al., 1992; Bellinger et al., 1987). In the Cleveland cohort, associations of cord, age 6 month, and concurrent blood Pb levels with MDI at age 2 years became null after adjusting for covariates including HOME score (Ernhart et al., 1988; Ernhart et al., 1987). However, 50% of the cohort was born to alcoholic mothers and may be less representative of the general U.S. population of children.

Table 5-4 Associations of blood Pb level with Bayley MDI in children ages 12 months to 3 years.

Study[a]	Study Population and Methodological Details (Presented in order of strength of study design and consideration for potential confounding)[a]	Blood Pb Timing and Levels (µg/dL)	MDI Assessment	Effect Estimate (95% CI)[b]
Bellinger et al. (1987)	249 children followed from birth (1979-1981) to age 2 yr, Boston, MA. **Prospective**. Recruitment from birth hospital. High follow-up participation. Participants had higher cord blood Pb level, SES, HOME score, maternal education and IQ, lower maternal age, were nonwhite. Regression model adjusted for maternal age, race, maternal IQ, maternal education, years of smoking, alcohol drinks/week in 3rd trimester, SES, HOME score, sex, birth weight, gestational age, birth order.	Prenatal (cord) Low: <3 Medium: 6-7 High: ≥ 10	Adjusted mean at age 2 yr High vs. low cord blood High vs. medium cord blood	 -4.8 (-7.3, -2.3) -3.8 (-6.3, -1.3)
Jedrychowski et al. (2009b)	444 children born 2001-2004 followed prenatally to age 3 yr, Krakow, Poland. **Prospective** cohort examining multiple exposures and outcomes. Recruitment from prenatal clinic. High follow-up participation. Log linear regression model adjusted for maternal education, birth order, prenatal smoking, sex, and within-subject MDI correlation. Did not consider potential confounding by HOME score.	Prenatal (cord) Geometric mean (range): 1.29 (0.44-5) Interval analyzed:1.2-1.3 = 10th-90th percentiles	Age 2 yr Age 3 yr	-2.6 (-5.0, -0.21) -2.3 (-4.3, -0.30)

Study[a]	Study Population and Methodological Details (Presented in order of strength of study design and consideration for potential confounding)[a]	Blood Pb Timing and Levels (µg/dL)	MDI Assessment	Effect Estimate (95% CI)[b]
Tellez-Rojo et al. (2006) Tellez-Rojo (2008)	193 children born 1997-1999 followed prenatally to age 2 yr, Mexico City, Mexico **Cross-sectional**. Recruitment from prenatal clinic or birth hospital. Participants had older, more educated mothers, lower cord blood Pb level, and slightly higher MDI. Log linear regression model adjusted for sex, maternal age, birth weight, maternal IQ, cohort. Considered potential confounding by other unspecified factors.	Concurrent Geometric mean: 2.9 Interval analyzed: 0.8-4.9 = range	Age 2 yr	-1.71 (-3.0, -0.42)
Claus Henn et al. (2012)	455 children born 1997-2000 followed prenatally to age 3 yr, Mexico City, Mexico **Prospective**, same cohort as above. No selective participation of subjects. Linear mixed effects regression adjusted for sex, hemoglobin, gestational age, maternal IQ, maternal education, blood Pb-blood Mn interaction. Did not consider potential confounding by HOME score.	Age 1 yr Mean (SD): 5.1 (2.6) Interval analyzed: 2.5-8.4 = 10th-90th percentiles	Ages 1 to 3 yr Blood Mn: <2.0 µg/dL Blood Mn: 2.0-2.8 µg/dL Blood Mn >2.8 µg/dL	 -3.0 (-5.22, -0.78) -0.07 (-0.39, 0.25) -2.2 (0, 4.44)
Hu et al. (2006)	146 children born 1997-1999 followed prenatally to age 2 yr, Mexico City, Mexico **Prospective**. Recruitment from prenatal clinic. Moderate follow-up participation. Eligible similar to non-eligible. Log linear regression model adjusted for sex, maternal age, current weight, height-for-age Z score, maternal IQ, concurrent blood Pb (in models examining blood Pb at other lifestages). Considered potential confounding by other unspecified factors.	Prenatal maternal 1st trimester Mean (SD): 7.1 (5.1)	Age 2 yr Prenatal 1st trimester Interval analyzed: 2.5 (10th percentile) -10)	 -0.91 (-1.8, -0.04)
		Prenatal maternal 3rd trimester Mean (SD): 6.9 (4.2)	Prenatal 3rd trimester Interval analyzed: 2.8 (10th percentile) - 10	-0.49 (-1.3, 0.31)

MDI = Mental Development Index, MTHFR = methylenetetrahydrofolate reductase

[a]Studies are presented in order of strength of study design and consideration for potential confounding. All Mexico City studies were kept together.

[b]Except where noted, effect estimates are standardized to a 1 µg/dL increase in blood Pb level for the lowest blood Pb range examined in the study or for blood Pb level up to 10 µg/dL.

A large study of 444 children in Krakow, Poland, found cord blood Pb-associated decrements in MDI at ages 2 and 3 years with lower cord blood Pb levels (median 1.23 µg/dL, 5th-95th: 1.24-1.34 µg/dL) than examined in other studies (Jedrychowski et al., 2009b) (Table 5-4). However, cord blood Pb levels reflect the pregnancy blood Pb levels of mothers. Evidence indicates increased mobilization of Pb from bone to blood in pregnant women (Sections 4.2.2.4 and 4.3.5.2). Thus, there is uncertainty regarding the Pb exposure scenarios that contribute to associations between cord blood Pb level and MDI in children. Jedrychowski et al. (2009b) estimated a larger decrease in MDI per unit

increase in cord blood Pb level among the 233 males than among the 223 females. Other observations have indicated increased susceptibility of the developing male central nervous system (CNS) to environmental insults (Moffitt et al., 2001). Although median cord blood Pb levels were similar in males (1.35 µg/dL) and females (1.41 µg/dL), the mean age 3-year MDI score was slightly lower among males than among females (101 and 105, respectively).

Multiple studies in various Mexico City cohorts reported associations of prenatal (maternal or cord) or child postnatal blood Pb levels with decrements in MDI in children between ages 1 and 3 years (Claus Henn et al., 2012; Pilsner et al., 2010; Surkan et al., 2008; Hu et al., 2006; Téllez-Rojo et al., 2006). Hu et al. (2006) compared associations among prenatal maternal blood Pb levels measured at different trimesters among 146 children at age 2 years. Increases in first trimester maternal blood Pb levels (whole blood or plasma) were associated with larger decreases in MDI scores than increased in maternal third trimester, cord, or child concurrent blood Pb levels (Table 5-4). These results were adjusted for sex, 2-year blood Pb level, height-for-age Z score, weight, maternal age, and maternal IQ. Model covariates did not include SES, maternal education, or HOME score; however, a larger list of unspecified potential confounding factors was considered.

Consistent with several findings for FSIQ, Tellez-Rojo et al. (2006) found larger effect estimates in children with lower blood Pb levels. In linear models, a 1 µg/dL increase in concurrent blood Pb level was associated with a -1.71 point (95% CI: -3.0, -0.42) decrease in MDI among 193 children with concurrent blood Pb levels <5 µg/dL and a -1.0 point (95% CI: -1.8, -0.26) decrease among 294 children with concurrent blood Pb levels <10 µg/dL. In a follow-up of the same cohort to age 3 years, Claus Henn et al. (2012) found inconsistent interactions between blood Mn and Pb levels. Investigators selected mid-range (2.0-2.8 µg/dL) blood Mn levels as the reference group based on previous observations that MDI scores were least affected by increases in blood Mn level in this group. Larger blood Pb-associated MDI decrements were found in the 91 children each with blood Mn levels <2.0 µg/dL and >2.8 µg/dL with age 1 year blood Pb level but not age 2 year blood Pb level. Adjustment for sex, gestational age, hemoglobin, maternal IQ, maternal education, and visit produced more negative effect estimates. Kim et al. (2009b) also found effect modification by blood Mn levels for the association between blood Pb level and FSIQ, but in older children ages 8-11 years (Section 5.3.2.1).

Other recent studies in Mexico City examined effect modification by maternal self-esteem, genetic variants, and nutritional status. Surkan et al. (2008) stratified data by the level of maternal self-esteem as reported by mothers. Higher age 2-year blood Pb level was associated with lower MDI score among children with mothers in the lowest three

quartiles of self-esteem but not among children with mothers in the highest quartile of self-esteem (Table 5-4). Model covariates included cohort, sex, parity, and maternal IQ, age, education, smoking, alcohol consumption, and self-esteem. These findings indicated that maternal psychosocial functioning may influence the effects of Pb on the mental development of young children.

In another study in Mexico City, higher cord blood Pb level was associated with a lower MDI score in children at age 2 years (-0.73 points [95% CI: -1.2, -0.23] in MDI per 1 µg/dL increase in cord blood Pb level in a linear model) (Pilsner et al., 2010). Investigators reported a lack of effect modification by genetic variants in the methylenetetrahydrofolate reductase (MTHFR) enzyme, which is involved in folate metabolism. The MTHFR 677 TT genotype produces an enzyme with lower metabolic activity, is associated with lower serum folate levels (Kordas et al., 2009), and in this Mexico City cohort, was associated with lower MDI score at age 2 years. Results from stratified analyses were not reported, thus differences in the magnitude of association between genotypes could not be compared.

Consistent with the prospective evidence, a recent cross-sectional analysis indicated an association between higher concurrent blood Pb level and lower MDI score children in the Philippines, ages 6 months to 3 years (Solon et al., 2008). Although HOME score, years of schooling of child, premature birth, region of residence, and maternal education and smoking were examined as potential confounding factors, adjustment was made in two stages: first, adjustment for blood Pb determinants and second, adjustment for MDI determinants. This method may not adequately control for the variance shared by blood Pb level and MDI. In this cohort, children with lower folate levels had larger Pb-associated decreases in cognitive function. Among children with folate levels $\leq$ 230 µg/mL, blood Pb level had an association with lower MDI scores in the range of 0.80 to 2.44 points. Among children with higher folate levels, blood Pb level was not estimated to have a negative impact. The results from this study indicated a moderating effect of folate on blood Pb levels as folate levels were not associated with MDI. Higher folate level has been associated with lower blood Pb level due to the role of folate in increasing Pb excretion by inhibiting the binding of Pb to blood elements.

In summary, evidence consistently indicates associations of higher blood Pb levels with lower MDI scores in children ages 2-3 years (Table 5-4). Key evidence was provided by prospective studies, in particular those that adjusted for maternal IQ and education, SES, birth outcomes, and HOME score (Wasserman et al., 1992; Bellinger et al., 1987). Several large studies contributed to the evidence (n = 146-592), and several studies had high to moderate follow-up participation, and nonselective loss-to-follow-up, which reduces the likelihood of selection bias. Higher blood Pb level was associated with lower

MDI scores in a few different cohorts in Mexico City and other populations, and while most adjusted for maternal education and IQ, they did not examine potential confounding by parental caregiving quality. The lack of association observed in the Cleveland cohort does not mitigate the otherwise compelling evidence, given the high prevalence of prenatal alcohol exposure in this cohort and the evidence in the Boston and Yugoslavia cohorts that adjusted for several potential confounding factors. MDI was associated with prenatal (cord or maternal) and concurrent blood Pb levels. Comparison among blood Pb levels at different lifestages did not consistently indicate a stronger effect on MDI of prenatal or postnatal Pb levels. Pb-associated decrements in MDI were found in populations with mean blood Pb levels 5-10 µg/dL. However, a cross-sectional analysis in children in Mexico City found a larger decrement in age 2 year MDI per unit increase in concurrent blood Pb level among children with blood Pb levels <5 µg/dL versus 5-10 µg/dL or <10 µg/dL (Téllez-Rojo et al., 2006). An association was found in children in Poland with lower cord blood Pb levels, median 1.23 µg/dL (Jedrychowski et al., 2009b). However, since cord blood Pb levels reflect blood Pb levels of mothers, which in turn are influenced by Pb mobilized from bone to blood, the specific Pb exposure scenario contributing to the observed associations is uncertain. Overall, while evidence indicates associations of higher prenatal and postnatal child blood Pb levels with lower MDI scores in young children (ages 2-3 years), the impact on later cognitive function is not certain since MDI scores do not necessarily predict later IQ in children with normal development.

5.3.2.3 Learning and Memory in Children

Epidemiologic Studies of Learning and Memory in Children

The small body of studies in the 2006 Pb AQCD did not clearly indicate associations between higher blood Pb level and poorer memory or learning (i.e., acquisition of new information) in children ages 5-17 years (Table 5-5). Studies used various tests to assess learning and memory, which may account for some of the heterogeneity observed in effect estimates. Evidence from prospective analyses in the Rochester, Boston, and Cincinnati cohorts was mixed, with an association found in the Rochester cohort at age 5 years (Canfield et al., 2004), associations in the positive and negative direction in the Boston cohort across the various tests and ages of blood Pb examined at ages 5 and 10 years (Stiles and Bellinger, 1993; Bellinger et al., 1991), and blood Pb-associated improved memory found in the Cincinnati cohort at age 15-17 years (Ris et al., 2004). Previous cross-sectional studies found associations between higher concurrent blood Pb levels and poorer learning and memory, including the large (n = 4,852) study of children

ages 6-16 years participating in NHANES (Lanphear et al., 2000). Several recent studies, all cross-sectional, also found associations between higher concurrent blood Pb level and poorer memory in children ages 6-16 years. Some were variants of previous studies (Krieg et al., 2010; Froehlich et al., 2007); others had limited implications because of little consideration for potential confounding (Counter et al., 2008; Min et al., 2007).

The prospective studies had smaller sample sizes (n = 148-195) than cross-sectional studies (n = 246-4,852) but greater examination of potential confounding. Further, recruitment of participants before or at birth, moderate to high follow-up participation, and in most cases follow-up not biased to higher blood Pb levels and lower cognitive function reduce the likelihood of selection bias (Table 5-5). Another strength was the examination of earlier childhood or lifetime average blood Pb levels, which better indicated the temporal sequence between Pb exposure and decrements in learning and memory.

Table 5-5 Associations between blood Pb levels and performance on tests of learning and memory in children.

Study	Study Population and Methodological Details (Prospective studies first, then cross-sectional studies. Within each category, presented in order of strength of study design)	Blood Pb Levels (µg/dL)	Memory/ Learning Test	Effect Estimate (95% CI)[a]
Canfield et al. (2004)	174 children born 1994-1995 followed from age 6 mo to 5 yr, Rochester, NY **Prospective**. Recruitment from study of dust control. 73% nonwhite. High follow-up participation, no selective attrition. Linear regression model adjusted for neonatal intensive care unit (NICU) admission, sex, age, spatial span length. Also considered potential confounding by prenatal smoking, household income, maternal IQ and education, ethnicity, HOME, breastfeeding duration, 1st prenatal visit, spatial working memory problem, birth weight, marital status, household crowding.	Lifetime (to age 5 yr) avg Mean (SD): 7.2 (3.6) Interval analyzed: 3.5 (10th percentile)-10	Spatial span total errors CANTAB Age 5 yr	-0.11 (-0.20, -0.02)[b]

CANTAB = Cambridge Neuropsychological Testing Automated Battery, CVLT = California Verbal Learning Test, WCST = Wisconsin Card Sorting Test, WISC-R = Wechsler Intelligence Scale for Children Revised, WRAML = Wide Range Assessment of Memory and Learning

[a]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level in the lowest range of blood Pb levels examined in the study or the interval from the 10th percentile to 10 µg/dL or the 90th percentile, whichever is lower.

[b]The direction of the effect estimate was changed such that a negative estimate represents poorer performance and a positive estimate represents better performance.

[c]Effect estimate compares test performance of children in higher blood Pb groups to children in lowest blood Pb group.

[d]Sufficient data were not provided to calculate 95% CI.

There were contrasting associations between blood Pb levels and memory in the Rochester and Boston cohorts at age 5 years (Canfield et al., 2004; Bellinger et al., 1991). Although different time periods of blood Pb level were examined, the population means were similar, ~7 µg/dL. In the Rochester cohort, a 1 µg/dL increase in higher lifetime average blood Pb level was associated with 0.11 (95% CI: 0.02, 0.20) more total errors on the spatial span memory task (i.e., errors in replicating a sequence pattern) with adjustment for neonatal intensive care unit (NICU) admission, sex, age, and spatial span length and consideration for several other factors (Table 5-5) (Canfield et al., 2004). Recent evidence extended findings to associations between poorer performance on a spatial working memory tasks and higher concurrent blood Pb levels (Froehlich et al.,

2007), which also reflect represent past and recent Pb exposure. In the recent analysis, associations were found with spatial span length (number of squares recalled correctly) with adjustment for HOME score, maternal IQ, and race; and with spatial working memory errors with adjustment for family income. In each analysis of the Rochester cohort, multiple associations were examined; however, there were consistent patterns blood Pb-associated decrements in cognitive function observed across the various indices of memory, learning, and executive function examined. Coherence for associations with performance on spatial span and spatial working memory tasks was found with evidence in rodents for Pb-induced impaired performance on visual-spatial memory tasks in the Morris water maze and working memory tasks in the radial arm maze, respectively (discussed below). In contrast, in the Boston cohort at age 5 years, concurrent blood Pb level was not associated with poorer memory, as assessed using the McCarthy Scale of Children's Abilities (Bellinger et al., 1991). These results were adjusted for more potential confounding factors than results from other studies (Table 5-5), including SES, maternal IQ, and HOME score. Higher age 2 year blood Pb level was associated with poorer memory at age 5 years, but the association lacked precision (Table 5-5).

In the Boston cohort at age 10 years, associations were inconsistent across the multiple tests of memory and learning and time periods of blood Pb levels (ages 1, 2, 5, 10 years) examined (Stiles and Bellinger, 1993). For example, higher age 1 year blood Pb level was associated with better memory (i.e., fewer errors in recalling word list) as assessed with the California Verbal Learning Test. In the Cincinnati cohort at age 15-17 years, higher earlier childhood (age 6.5-year) blood Pb level also was associated with better memory (composite score of various subtests of the California Verbal Learning Test with adjustment for similar potential confounding factors plus adolescent marijuana use (Ris et al., 2004). In two independent Boston-area cohorts examined at different ages, poorer learning (number of trials to sort cards properly or number of categories achieved) as assessed with the Wisconsin Card Sorting Test (WCST) was associated with higher age 1 year blood Pb level in children ages 10 years (Stiles and Bellinger, 1993) and with higher childhood tooth Pb levels in young adults ages 19-20 years (-0.6 categories [95% CI: -1.0, -0.21] per natural log unit increase in tooth Pb level [collected from age 5-8 years], with adjustment for parental IQ, maternal age and education, SES, sex, birth order, current smoking status, drug use, and alcohol use) (Bellinger et al., 1994a). In the younger cohort age 10 years, decrements in learning as assessed by performance on the WCST were not consistently found across the various ages of blood Pb level examined (Stiles and Bellinger, 1993).

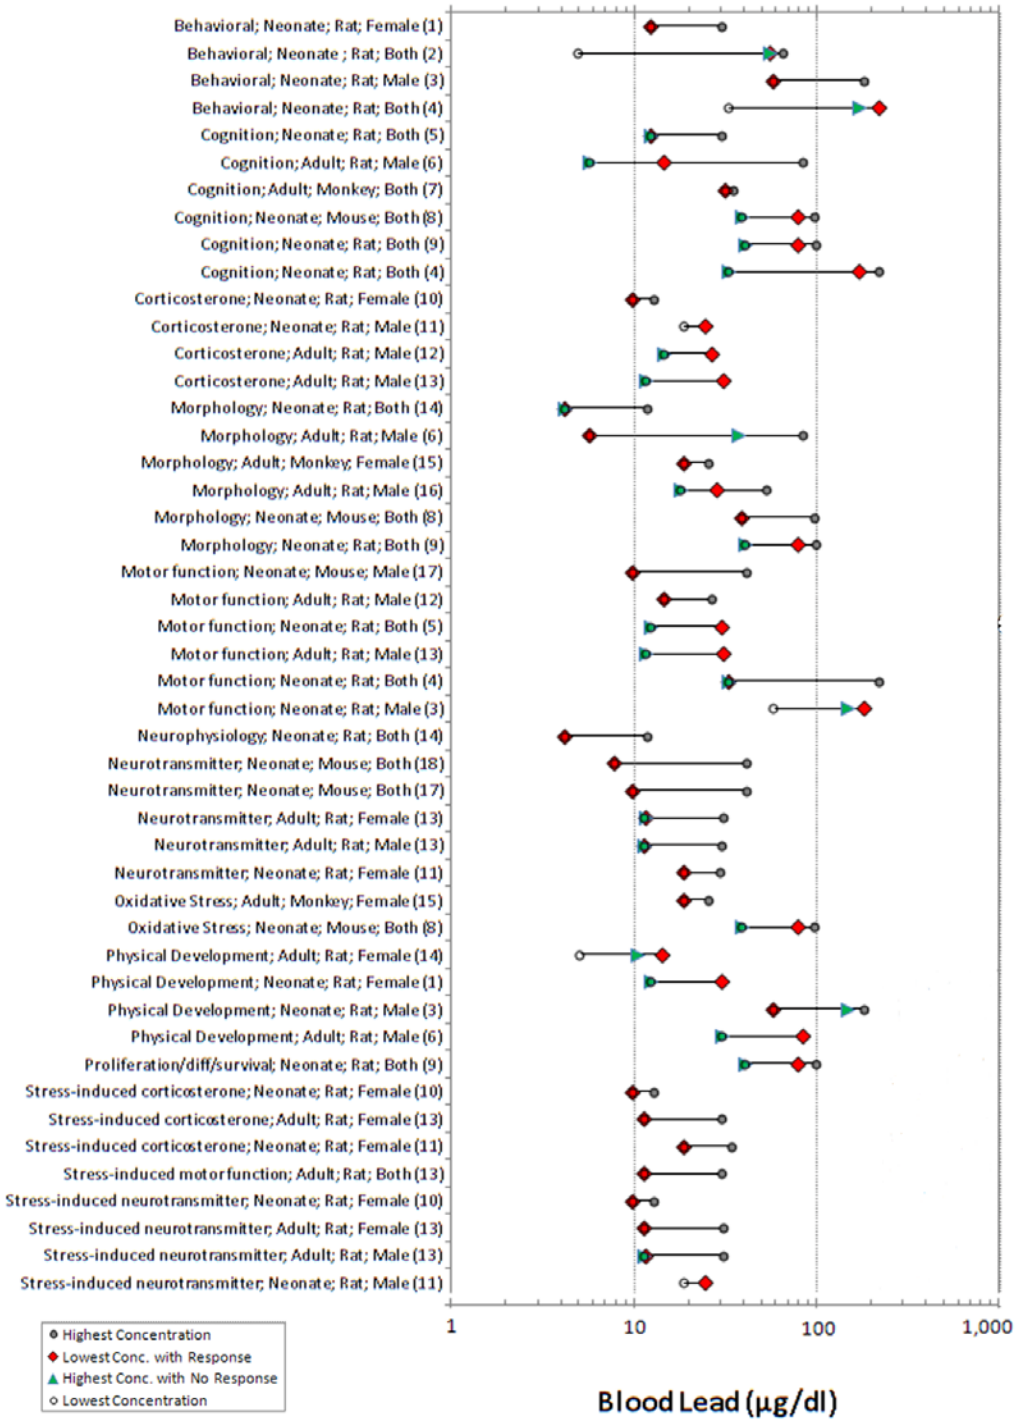
The cross-sectional studies examined potential confounding by parental education and SES, but a notable omission was consideration for HOME score. Chiodo et al. (2004) found a concurrent blood Pb-associated decrement in spatial memory with adjustment for

HOME score. However, the results may lack generalizability because of the high prevalence of prenatal alcohol exposure. HOME score was not associated with memory in every study. For example, in the Rochester cohort, only household income remained significantly associated with total errors in the spatial working memory task and was included in the final model (Froehlich et al., 2007). Therefore, the confounding factors may vary among populations. Most cross-sectional studies found Pb-associated decrements in memory in populations with mean concurrent blood Pb levels 5-8 µg/dL. Despite the lack of information on HOME score, the cross-sectional analyses of children participating in NHANES III had several strengths, including large sample sizes (n = 760-4,852), high participation rates, lower likelihood of selection bias due to the examination of multiple risk factors and outcomes, nationally-representative results, and examination of the shape of the concentration-response relationship (Krieg et al., 2010; Lanphear et al., 2000). An increase in concurrent blood Pb level was associated with a larger decrement in digit span score in adolescents ages 12-16 years (Krieg et al., 2010) than children 6-16 years (Lanphear et al., 2000); however, the influence of higher past Pb exposures is likely greater in older children. In the analysis of children ages 6-16 years, Lanphear et al. (2000) estimated the largest decrement in memory score per unit increase in blood Pb level in children with concurrent blood Pb levels <2.5 µg/dL (-0.25 [95% CI: -0.58, 0.08] points per 1 µg/dL increase in concurrent blood Pb level versus -0.05 [95% CI: -0.09, -0.01] among all subjects). A nonlinear concentration response relationship also was found among children ages 7 years living near a metal foundry in Torreon, Mexico, with a larger Pb-associated decrement in memory found among children with concurrent blood Pb levels <10 µg/dL (Kordas et al., 2006).

Toxicological Studies of Learning and Memory

As described in the preceding sections, blood Pb levels are consistently associated with decrements in FSIQ in children but show more variable associations with performance on neuropsychological tests of learning and memory. A relationship between Pb exposure and cognitive function decrements is supported further by evidence for Pb-induced impairments in memory and learning in animals. The 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb-induced impaired memory and learning primarily in animals with Pb exposures that resulted in blood Pb levels 30-50 µg/dL; however, some studies observed impairments in rodents (pre- and/or post-natal Pb exposure) and monkeys (lifetime postnatal Pb exposure) with blood Pb levels 14-25 µg/dL (Altmann et al., 1993; Rice and Karpinski, 1988; Gilbert and Rice, 1987). Several recent studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels in the range relevant to humans, 8-17 µg/dL (Cory-Slechta et al., 2010; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007). Effects in animals with lower blood Pb levels generally

were found with gestational/lactational Pb exposures. Results from toxicological studies on learning as well as other nervous system endpoints that provided concentration-response information (i.e., those with multiple Pb exposure concentrations) are shown in Figure 5-3 and associated Table 5-6. These results demonstrate the coherence among inter-related CNS changes induced by Pb exposure in animals, including deficits in CNS development and plasticity and alterations in neurotransmitters, which mediate cognitive function.



Note: This figure illustrates nervous system effects associated with Pb exposure in studies that examined multiple exposure concentrations. Dosimetric representation reported by blood Pb level. (ID corresponds to studies described in Table 5-6)

Figure 5-3 Summary of Pb exposure-nervous system concentration-response information from toxicological studies.

Learning and Memory - Morris Water Maze

In the Rochester cohort of children, blood Pb level was associated with poorer performance on tests of spatial memory (Table 5-5). In animals, spatial memory has been tested using the Morris water maze apparatus. The Morris water maze can be used to test spatial memory and learning ability by assessing the time or distance taken for a rodent to swim to a submerged platform using visual cues and in subsequent trials with the platform removed, the time spent in the previous location of the platform. The 2006 Pb AQCD (U.S. EPA, 2006b) reported mixed effects of Pb on memory; some studies found Pb-induced impaired memory in animals whereas others found improved memory with Pb exposure (U.S. EPA, 2006b). Evidence was more consistent for Pb-induced impairments in long-term memory, i.e., stored information, which was found in animals with gestational, gestational/lactational, or gestation/lifetime Pb exposure producing blood Pb levels 23-32 µg/dL (Yang et al., 2003; Jett et al., 1997; Kuhlmann et al., 1997). Using the Morris water maze, Jett et al. (1997) found an effect of gestational plus lactational Pb exposure of female rats (Pb acetate in maternal feed 10 days prior to mating to PND21) on long-term memory but not working memory, which is memory for information that changes frequently that is not stored permanently. Kuhlmann et al. (1997) compared various lifestages of Pb exposure and found impaired learning and long-term memory using the Morris water maze in Long Evans rats exposed to Pb during gestation and lactation (via maternal diet) or over a lifetime from gestation through adulthood each producing peak blood Pb levels of 59 µg/dL, which are higher than those relevant to humans. Pb exposure during only the post-weaning period, producing a more relevant blood Pb level of 26 µg/dL did not affect memory.

In contrast with Kuhlmann et al. (1997), recent evidence points to impairments in memory and learning as assessed with the Morris water maze with postweaning Pb exposure, albeit with higher blood Pb levels than relevant to humans. Impaired learning, i.e., slower decrease in time to escape from the Morris water maze across training trials, was found in weanling Sprague-Dawley male rats exposed to 400 or 800 mg/L Pb acetate for 8 weeks in drinking water (Fan et al., 2010; Fan et al., 2009a). Further, various dietary supplements (oral gavage of methionine, taurine, Zn, ascorbic acid or glycine) or methionine-choline given before or concomitantly with Pb exposure in these weanling males mitigated the effect of Pb on escape latency to resemble that of control pups at the end of training (Fan et al., 2010; Fan et al., 2009a). In Fan et al. (2009a), Zn and methionine given before Pb exposure attenuated Pb-induced impairments in spatial memory and learning, whereas glycine, taurine, vitamin C, vitamin B1, tyrosine had no effect (blood Pb levels ranged from 7 to 70 µg/dL depending on nutrient status and recovery time). In Fan et al. (2010), Pb-exposed rat pups (blood Pb level 50.2 µg/dL) showed deficits in retaining information about the platform location after test day 2 and 3. Concurrent methionine-choline treatment mitigated these impairments in spatial memory. The action of methionine, a source of sulfur, may be attributable to its function

as a chelator and/or free-radical scavenger. Choline is important for cell membranes and neurotransmitter synthesis (Zeisel and Blusztajn, 1994), and unrelated to Pb exposure, choline supplementation of rats PND16-PND30 was shown to attenuate normal age-related declines in spatial memory (Meck et al., 2007).

Consistent with Kuhlmann et al. (1997), other recent studies found impairments in learning and memory in animals as assessed using the Morris water maze with gestational/lactational Pb exposures, albeit at higher concentrations than those relevant to humans. In Li et al. (2009c), rodents were exposed GD1-PND21 to Pb acetate via the drinking water of dams (1,000-10,000 ppm) and had corresponding blood Pb levels of 40-100 µg/dL at PND21. Beginning at weaning, learning and spatial memory were assessed in pups with a reversal procedure in the Morris water maze. Pb-exposed pups with blood Pb levels of 80 and 100 µg/dL had statistically significant increases in escape latency, indicating impaired spatial memory and learning (Li et al., 2009c). The pups in Li et al. (2009c) were not separated by sex. Cao et al. (2009) found that long-term postnatal Pb exposure from birth (2,000 ppm Pb acetate) impaired spatial memory in male Wistar rats as adults (PND81-90), and these effects were exacerbated by long-term administration of melatonin (3 mg/kg by gastric gavage, 60 days from weaning). Mechanistic support for effects on learning and memory was provided in this study by observations in the hippocampal dentate gyrus that Pb exposure also impaired long-term potentiation (LTP), a major cellular mechanism underlying learning and memory.

Working Memory – Delayed Spatial Alternation

Working memory also can be measured by testing delayed spatial alternation (DSA). In DSA, an animal receives rewards by alternating responses between two locations or levers. This test requires working memory because the correct response changes between trials, and the animal must determine which response is correct based on memory of its previous response. Impaired working memory is indicated by increased response errors, decreased percent of correct responses, and increased response perseverative errors (i.e., repeatedly pressing the same lever without moving to the other lever when the reward is moved. Studies detailed in earlier Pb AQCDs showed that Pb-exposed animals had deficits in working memory as assessed with DSA (Alber and Strupp, 1996; Rice and Gilbert, 1990b; Rice and Karpinski, 1988; Levin et al., 1987). Studies in nonhuman primates showed that there were multiple lifestages and durations of Pb exposure that induced poorer performance on DSA tasks, including lifetime from birth or later postnatal (i.e., post-weaning to time of testing) (Rice and Gilbert, 1990b; Rice and Karpinski, 1988; Levin et al., 1987). Pb-induced impairments in DSA task performance have been observed less consistently in rats with juvenile only or juvenile to adult

exposure. In fact, postweaning Pb exposure was shown to increase accuracy in performance on DSA tasks in rodents (Cory-Slechta et al., 1991).

Learning and Memory - Y Maze

The three-branch radial Y-maze test evaluates learning as the number of days required to learn the maze (90% correctly). The Y-maze has a light at the end of one of the branches. The branch with the illuminated light is the safe area whereas the other two branches are electrified and cause a mild electric shock when entered. The spatial memory test assessed by the Y-maze test shares homology with the spatial working memory test conducted by Froehlich et al. (2007) in the Rochester cohort, which require children to search boxes for a reward and avoid returning to boxes where the reward was previously found. A recent study using the Y-maze showed impaired learning in Wistar albino rat offspring exposed to Pb from lactation to adulthood up to 12 weeks of age (300 mg/dL Pb acetate in dam drinking water and then in offspring drinking water postweaning) (Niu et al., 2009). Pb induced statistically significant impairments in learning at 8, 10 and 12 weeks of age but not age 6 weeks. These effects on learning were found with blood Pb levels relevant to humans, 17 µg/dL, as measured at age 6 weeks. Mechanistic support for Pb-induced learning impairments was provided by concomitant observations of Pb-induced attenuation in levels of hippocampal glutamate (Section 5.3.11.4), which mediates signaling pathways involved in LTP.

Learning - Schedule-Controlled Behavior Testing

The 2006 Pb AQCD described the effects of Pb exposure on learning in animals as measured with schedule-controlled behaviors using Fixed Interval (FI) or Fixed Ratio (FR) operant conditioning reinforcement schedules and indicated differential effects by Pb exposure concentration, with low-level (e.g., 11 µg/dL) and high-level Pb (peak levels of 115 µg/dL) exposures increasing and decreasing FI response rate, respectively. This nonlinear response has been examined further in recent work by the Cory-Slechta laboratory, much of which also examined the interaction between stress and Pb exposure. Impaired performance in FI testing with Pb exposure also supports the effects of Pb on attention-related behavioral problems (Section 5.3.3.1).

Recent evidence indicated that certain learning impairments induced by certain levels of Pb exposure were modifiable. Female rats were exposed to 300 ppm Pb acetate via dam drinking water from birth through lactation PND1-PND21 and 30 ppm via their own drinking water to PND30. Rats subsequently administered succimer PND31-PND52 (twice daily by oral gavage, resulting in blood Pb level 2.8 µg/dL) performed better on visual discrimination tasks than did the rats exposed to Pb alone (blood Pb level at

PND52: 12.6 µg/dL) (Stangle et al., 2007). Brain Pb levels also were lower in the Pb+succimer group (196 ng/g) than Pb-only group (1,040 ng/g). Succimer alone in the absence of Pb exposure resulted in some cognitive impairment in this study, and rats given succimer after a higher Pb concentration (300 ppm, blood Pb level 8.5 µg/dL) did not have better learning ability than rats exposed to 300 ppm Pb alone (blood Pb level: 31 µg/dL). Therefore, succimer administration may not completely alleviate the effects of Pb exposure on learning impairments.

Learning Ability with Stress

The combined paradigm of Pb exposure and stress experienced by a laboratory animal has been examined by the Cory-Slechta laboratory, which has focused on the common pathway of altered HPA axis and brain neurotransmitter levels. Depending on the timing of stress and Pb exposure concentration, greater impairments in learning were found in animals with dietary Pb exposure that resulted in blood Pb levels relevant to humans when combined with stress. Evidence additionally indicates that associations of Pb exposure and stress with learning deficits (multiple schedule of repeated learning and performance in females) may be related to aberrations in corticosterone and dopamine. As indicated in Figure 5-3 and Table 5-6, Pb exposure with stress has been shown to increase corticosterone levels and exacerbate Pb-induced dopamine release and learning impairments. For example, learning deficits in female rat offspring at age 2 months were enhanced following lifetime Pb exposure combined with prenatal stress, i.e., maternal restraint (Cory-Slechta et al., 2010). This exposure paradigm involved exposure of dams to Pb acetate from 2 months prior to mating through lactation and exposure of their pups from a mixed sex litter via drinking water Pb (50 ppm) through the remainder of their lifetime (2 months). The peak blood Pb levels of pups (age 5-6 days) ranged from 10 to 13 µg/dL. Learning impairments were found in repeated learning assessments but not performance assessments. Pb/stress was found to increase the total number of responses required to learn a sequence. Pb/stress exposure also affected dopamine from the frontal cortex and dopamine turnover in the nucleus accumbens, which are processes underlying cognition. Also, Pb-exposed offspring with and without maternal stress exposure had statistically significant decreases in hippocampal nerve growth factor versus controls.

Another study of lifetime Pb exposure (50 or 150 ppm Pb acetate in drinking water to dams from 2 weeks before pregnancy though lactation and to offspring thereafter) indicated a potentiation of effects on learning with Pb and stress co-exposure, with stress given prenatally via dams or postnatally to offspring. Lifetime 50 ppm Pb exposure plus prenatal or postnatal stress resulting in blood Pb levels 11-16 µg/dL decreased the post-reinforcement pause (PRP) period in female offspring when examined starting at age 2 months (Rossi-George et al., 2011) (Table 5-7, rightmost column). Animals with

150 ppm Pb exposure and blood Pb levels 25-33 µg/dL had decreased PRP only with prenatal stress. Within the FI schedule, the PRP represents timing capacity or proper temporal discrimination and refers to the period during which the animal waits or pauses before depressing the lever for a reward. In this case, decreased pause or PRP interval in Pb plus stress-exposed animals indicates that they started responding earlier than did controls. These results also point to an effect of Pb on increasing impulsivity (Section 5.3.3.1). Separately, the overall FI response rate, which also indicates impulsivity (i.e., rate of not withholding responses), was significantly increased with 50 ppm Pb exposure alone and with co-exposure to maternal or offspring stress. At 150 ppm, Pb increased FI response rate only with co-exposure to stress (maternal or offspring). Biochemical analysis revealed alterations in frontal cortex norepinephrine, reductions in dopamine homeostasis in the nucleus accumbens, and enhancement of the striatal monoamine system as possible mechanistic contributions to Pb-induced impairments in learning.

Table 5-7 Summary of effects of maternal and lifetime Pb exposure on FI performance observed by Cory-Slechta and colleagues.

	Maternal Pb[b]		Lifetime Pb[c]	
Pb (ppm)	Overall rate[a]	PRP[a]	Overall rate[a]	PRP[a]
0 ppm:				
0-PS	No Significant Effect	No Significant Effect	No Significant Effect	No Significant Effect
0-OS	No Significant Effect	*↓ -23%	No Significant Effect	No Significant Effect
50 ppm:				
50-NS	No Significant Effect	No Significant Effect	*↑ 95%	No Significant Effect
50-PS	No Significant Effect	No Significant Effect	*↑ 79.2%	*↓ -42%
50-OS	*↑ 64.9%	No Significant Effect	*↑ 74.7%	* ↓-39.3%
150 ppm:				
150-NS	*↑ 42.4%	*↓ -30.3%	No Significant Effect	No Significant Effect
150-PS	No Significant Effect	*↓ -25.7%	*↑ 90.7%	*↓ -44.7%
150-OS	*↑ 59.2%	No Significant Effect	*↑ 78.5%	No Significant Effect

[a]Based on calculation of group mean values across session block post-stress challenge for both maternal and lifetime Pb exposure studies. All calculations represent percent of 0-NS control values; ↑ represents increase; ↓ represents decrease.

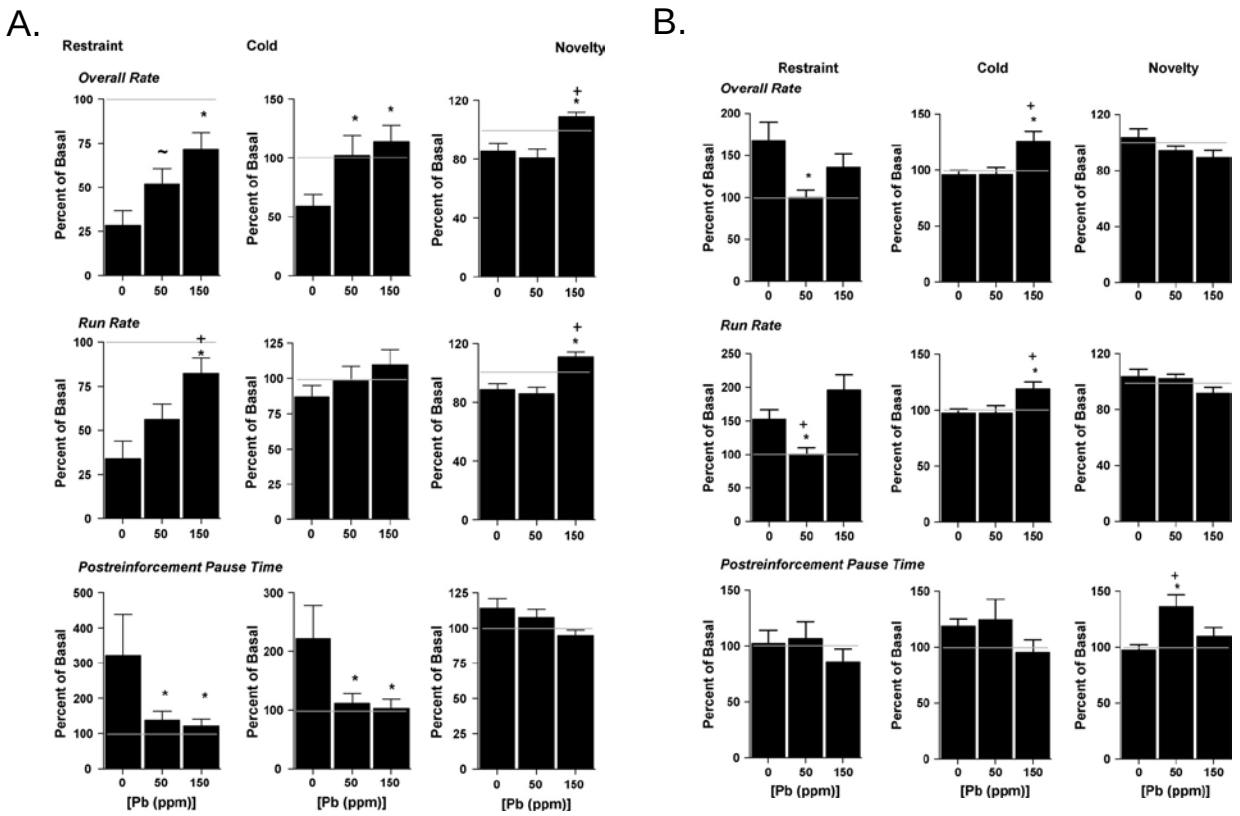
Notes:
PRP = Post-reinforcement pause; PS = Prenatal (maternal stress); OS= Offspring stress.

Overall results demonstrated that lifetime Pb exposure (right column) with or without prenatal stress induced learning deficits in female rats as demonstrated by an increase in overall rate and decreased PRP. Mechanistically, these authors proposed that associations of Pb and stress with learning deficits may be related to aberrations in corticosterone and dopamine. Prenatal Pb exposure alone (left column) induced similar responses during testing at age 2 months.

A separate investigation from the same laboratory similarly indicated a potentiation of effects with Pb and stress co-exposures but with developmental Pb exposure from two months prior to mating through lactation (50 or 150 ppm Pb acetate in drinking water) (Virgolini et al., 2008a). Dams were subject to restraint stress at GD16-GD17. Prenatal stress or Pb exposure alone did not affect FI performance in offspring. Compared with controls, marked increases in response rates on FI performance were found in the 50 ppm Pb plus prenatal stress female offspring at age 2-3 months, whose mean blood Pb level was 19 µg/dL at weaning. Using the same Pb exposure protocol, Virgolini et al. (2008b) expanded evidence for Pb-stress interactions through the examination of the effects of additional adult intermittent stress (cold, novelty or restraint) on FI performance, corticosterone, and dopamine. Compared with females with stress but no Pb, female offspring with adult intermittent restraint and cold stress and higher dose Pb (150 ppm) had statistically significant increases in FI response rate and decreased PRP, i.e., increased impulsivity (Figure 5-4, A panel). Male offspring showed decreased FI response rates due to decreased run rate with restraint stress at the lower Pb dose (50 ppm) (Figure 5-4, B panel). At the higher dose of Pb, males showed increased FI response rates and increased run rates with cold stress.

Pb exposure over various developmental windows in rodents has been shown to affect the HPA axis, as measured by the levels of corticosterone, the major glucocorticoid involved in stress responses in rodents. Thus, modulation of corticosterone may provide a mechanistic explanation for learning deficits (FI testing in females) found with Pb and stress co-exposure in rodents. As examined by the Cory-Slechta laboratory, exposure to Pb induced differential changes in corticosterone levels in each sex, depending on the age of the animal and the timing of exposure, developmental (gestational and lactational), post-weaning, or lifetime (Rossi-George et al., 2011; Cory-Slechta et al., 2010; Virgolini et al., 2008a).



Note: * denotes significantly different from 0 ppm Pb. ~denotes p = 0.07. + denotes significantly different from the 50 ppm Pb group. Each column presents results for a particular stressor (restraint, cold, novelty). In females (panel A), gestational/lactational 50 and 150 ppm Pb exposure increased overall rate and decreased post-reinforcement-pause time over that of cold or restraint stress given in adulthood. In males (panel B), gestational/lactational Pb exposure did not alter the effects of the stressors.

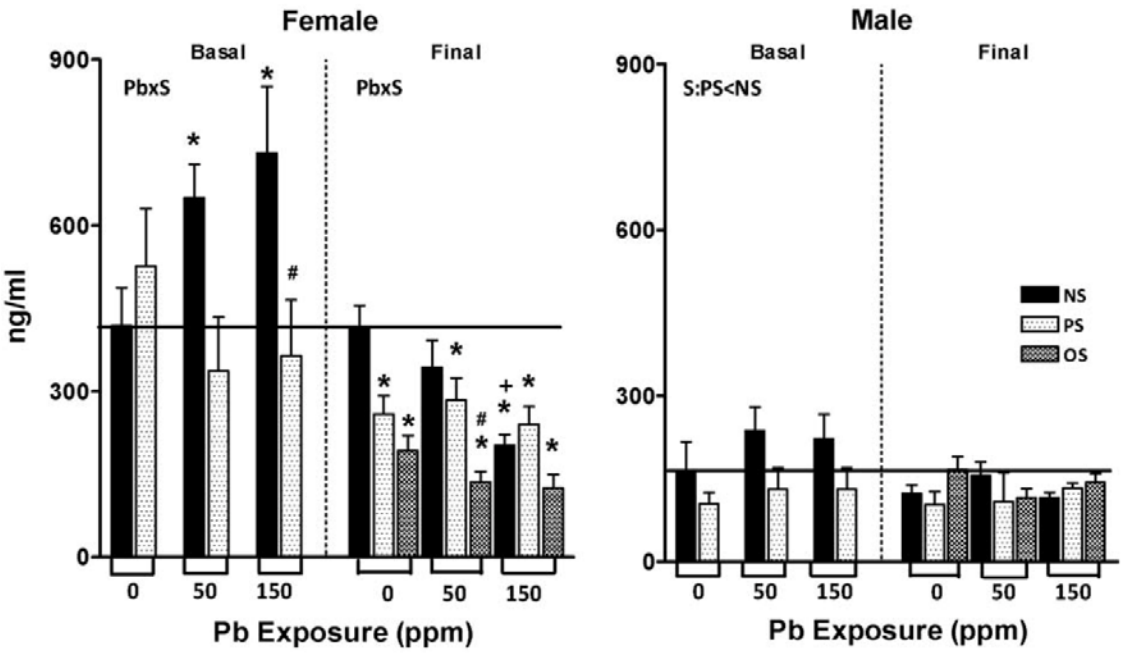
Figure 5-4 Changes in Fixed Interval performance in (A) female and (B) male offspring with gestational/lactational Pb exposure plus various stressors given in adulthood.

Because animals that are used for FI testing are regularly handled by laboratory personnel and often participate in other tests of cognition, their baseline level of stress may be skewed from that of a laboratory animal that constantly remains in a cage without daily handling. Because effects on the HPA axis are of interest to Pb researchers, the baseline corticosterone levels of animals that have participated in behavior testing (FI) and those who have not (NFI) have been compared after gestational/lactational Pb exposure. Virgolini et al. (2008b) found that baseline corticosterone levels were significantly different between FI and NFI animals. Also, the effect of combined gestational/lactational Pb exposure plus maternal stress on corticosterone was compared in FI and NFI animals. At the baseline age of 4-5 months, Pb exposure with or without stress did not induce differences in corticosterone levels in FI females but did in males (Virgolini et al., 2008b). In the FI males, 50 ppm Pb exposure decreased corticosterone versus control (no Pb exposure), and 150 ppm Pb exposure elevated corticosterone versus control. In male NFI animals, a U shaped concentration-response was found, with 50 ppm Pb exposure reducing corticosterone over than in the controls or with 150 ppm Pb exposure. In the NFI males, stress did not affect corticosterone levels or interact with the effect of Pb exposure. NFI females exposed to 150 ppm Pb had significantly elevated corticosterone versus control (no Pb exposure). These data demonstrate that behaviorally tested animals have altered HPA axis and altered responses to Pb exposure versus animals that are housed under conditions without daily handling by caregivers.

Lifetime Pb exposure beginning in gestation (150 ppm drinking water of dams from 2 months prior to mating through lactation, then continuing in offspring water) induced increases in basal (age 2 months, before behavioral testing) corticosterone only in female offspring but not final (age 10 months, after testing) corticosterone in either female or male offspring (Rossi-George et al., 2011) (Figure 5-5). The Pb-related increase in corticosterone was found in animals with blood Pb levels of 19 and 31 µg/dL measured at PND21. Pb-stress interactions were observed at age 2 months but not 10 months (final, after behavioral testing). At age 2 months, Pb plus stress attenuated the Pb-induced elevations in corticosterone to baseline levels (Figure 5-5). By 10 months of age, these offspring had lower corticosterone concentrations versus control animals. In males, corticosterone levels were not affected significantly by Pb and/or stress at 2 (basal) or 10 (final) months of age (Figure 5-5) (Rossi-George et al., 2011).



Note: Corticosterone levels are noted on the y-axis. *denotes significantly different from NS control (Black bars); # denotes significantly different from corresponding Pb-NS value; + differs from 50-NS. (0, 50, 150 ppm) and/or stress (PS [dam stress, white bar with black dots] or OS [PS followed by offspring stress, black bar with white spots]). Basal measurements were taken at 2 months of age, prior to the initiation of behavioral testing and final measurements were taken at 10 months, after behavioral testing.

Source: Rossi-George et al. (2011)

Figure 5-5 Mean basal and final corticosterone levels of female and male offspring exposed to lifetime Pb.

Pb-stress effects on corticosterone have not been consistent. In another study, gestational plus lactational Pb (50, 100 ppm) did not affect baseline corticosterone levels in females and there was no interaction with stress (Virgolini et al., 2008a). In males, stress increased baseline corticosterone in the 150 ppm Pb group. In animals given intermittent stress as adults and not behaviorally tested, Pb decreased corticosterone levels in females but not males, which may explain the observations of Pb plus stress increases in decreases in FI response rates in females (Virgolini et al., 2008b). Post-weaning exposure of male rodents to Pb (PND21-age 5 months) produced a U-shaped concentration-response for corticosterone prior to FI testing, with a significant decrement in basal corticosterone levels in the 50 ppm exposure group versus control and the 150 ppm Pb group (Virgolini et al., 2005). Lifetime Pb exposure and prenatal stress both reduced corticosterone in animals behaviorally tested at age 4 months but not in animals at age 11 months not behaviorally tested (Cory-Slechta et al., 2010).

Another study examined the effects of Pb acetate on the HPA axis but examined the interaction with an outside stress administered using control vehicle injections (Rossi-George et al., 2009). The corticosterone response to this vehicle injection stress was

prolonged in a nonlinear concentration-dependent manner in both sexes with the most profound effects observed at the lower 50 ppm Pb dose. Maternal stress also prolonged the corticosterone stress response to vehicle injection and enhanced the Pb effect in males. To test the negative feedback of the HPA axis, exogenous dexamethasone (DEX) was administered to suppress endogenous corticosterone. The DEX test revealed HPA axis hypofunction. Specifically, Pb and Pb plus maternal stress initially reduced the ability of DEX to suppress corticosterone. With time, the effect of DEX in males induced prolonged corticosterone suppression or failure to return to baseline as was observed in control animals. Rossi-George et al. (2011) additionally found that Pb and/or maternal stress significantly impacted the negative feedback by increasing nuclear glucocorticoid receptor levels. In summary, prenatal Pb exposure induced HPA negative feedback hypofunction in both male and female offspring with an inverse U concentration-response relationship. This negative feedback loop was impacted more at the lower Pb dose (50 ppm) versus the higher dose (150 ppm) (Rossi-George et al., 2011).

To summarize the results for Pb-stress interactions in animals (Table 5-6), lifetime Pb exposure when combined with stress was found to exacerbate learning impairments compared with Pb exposure or stress alone, although not across all tests or Pb doses. The interaction between Pb and stress may be mediated via effects on corticosterone and dopamine. Lifetime Pb exposure was found to increase basal (at age 2 months) corticosterone levels in females, and co-exposure to stress attenuated the response (Rossi-George et al., 2011; 2009). Males given lifetime Pb exposure had no statistically significant corticosterone response to Pb exposure; whereas males with gestational/lactational Pb exposure had statistically significant decreases in corticosterone at 5 months of age in the 50 ppm exposure group only (but not in 150 ppm Pb exposure group). On the other hand, females had concentration-dependent corticosterone responses to Pb exposure in both exposure models (lifetime Pb exposure and gestational/lactational Pb exposure). Maternal stress alone also led to HPA axis negative feedback hypofunction in offspring. Pb exposure plus maternal stress enhanced negative feedback in males and attenuated this effect in females. Pb exposure with or without maternal stress prolonged the effect of DEX-dependent corticosterone suppression in males. These data together show that HPA axis alterations could provide a link for interactions found between Pb and stress in impairing learning.

5.3.2.4 Executive Function in Children

Epidemiologic evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006b) indicated associations between higher blood or tooth Pb levels and poorer performance on tests of executive function in children and young adults. Associations were found with indices of executive function such as strategic planning, organized search, flexibility of thought and action to a change in situation, and control of impulses (described in greater detail in Section 5.3.3.1). Prospective analyses in two Boston area and the Rochester cohorts provided key evidence with examination of blood Pb levels preceding executive function testing and adjustment for several potential confounding factors (Canfield et al., 2004; 2003b; Bellinger et al., 1994a; Stiles and Bellinger, 1993). Further, recruitment of participants before or at birth, moderate to high follow-up participation, and in most cases follow-up not biased to higher blood Pb levels and lower cognitive function increase confidence that the observed associations are not due to selection bias (Table 5-8). Among the few recent cross-sectional studies, most found concurrent blood Pb-associated decrements in executive function, including an analysis of the Rochester cohort (Froehlich et al., 2007). Evidence from other recent studies had weaker implications due to the limited consideration of potential confounding (Nelson and Espy, 2009; Vega-Dienstmaier et al., 2006). Several of the prospective and cross-sectional studies performed multiple tests of cognitive function, including executive function. However, except for Stiles and Bellinger (1993), a consistent pattern of association was found across the various tests performed. Thus, the evidence does not appear to be biased by associations found by chance alone.

Studies in children found Pb-associated decreases in executive function using various tests including the Intra-Extra Dimensional Set Shift, WCST, and Stoop test (Table 5-8). As discussed below, studies in animals also demonstrated Pb-induced decrements in executive function, including rule learning and reversal, which also were associated with blood Pb levels in children. This coherence between findings in animals and humans for analogous domains further supports a relationship between Pb exposure and decrements in cognitive function. Additional biological plausibility for Pb-associated decrements in executive function is provided by toxicological evidence for Pb-induced changes in the availability of dopamine (Section 5.3.11), a neurotransmitter that affects executive functions mediated by the prefrontal cortex. Recent work shows that executive function in animals is affected by N-Methyl-D-aspartic acid or N-Methyl-D-aspartate (NMDA) receptors and dopamine-like receptors (Herold, 2010), which are two well-characterized targets of Pb.

In the Boston cohort, children tested at a relatively older age (10 years), when testing is more reliable, a 1 µg/dL increase in age 5 year blood Pb level was associated with 0.05 (95% CI: 0.01, 0.09) more perseverative errors on the WCST (errors in sorting cards according to a change in rule) (Stiles and Bellinger, 1993). In this cohort, results were inconsistent across the various cognitive tests. However, associations were more consistent for executive functions assessed by the WCST. In another cohort ages 19-20 years from towns around Boston, higher tooth Pb levels (from ages 5-8 years) were associated with more errors on the WCST in sorting by the set rules and poorer performance on the Stroop Color and Color-word tests, which test the ability of subjects to shift focus to another dimension of stimulus that defines correct responding (Bellinger et al., 1994a).

Table 5-8 Associations between blood or tooth Pb levels and performance of tests of executive function in children and young adults.

Study	Study Population and Methodological Details (Presented first for prospective studies then for cross-sectional studies. Within each category, results are presented in order of strength of study design)	Blood Pb Levels (µg/dL)	Executive Function Test	Effect Estimate (95% CI)[a]
Stiles and Bellinger (1993)	148 children followed from birth (1979-1981) to age 10 yr, Boston, MA area **Prospective**. Recruitment at birth hospital. Moderate follow-up participation, participants had higher SES and HOME score. Linear regression model adjusted for HOME score, family stress, race, marital status (5 yr blood Pb), HOME score, family stress, maternal age and race, birth weight, # daycare situations to age 57 mo (concurrent). Surkan et al. (2007)	389 children ages 6-10 yr, Boston, MA ,Farmington, ME **Cross-sectional**. Recruitment from trial of amalgam fillings. High participation rate. Higher participation of white children in Maine. Analysis of covariance adjusted for caregiver IQ, child age, SES, race, and birth weight, Also considered potential confounding by caregiver education and marital status, parenting stress, and maternal utilization of prenatal or annual health care but not parental caregiving quality.	Concurrent Mean (SD): 2.2 (1.6)	 Perseveration errors, WCST Stroop color-word interference	Blood Pb level 5-10 vs. 1-2 µg/dL[d] -9.19 (-14.6, -3.7) 0.75 (-1.6, 3.1)
Chiodo et al. (2004)	246 children, age 7.5 yr, Detroit, MI area **Cross-sectional**. Recruitment at prenatal clinic. All African American High prevalence of prenatal alcohol exposure. High participation rate. Log linear regression model adjusted for SES, family functioning, # children <18 yr, caregiver vocabulary, prenatal alcohol use, caregiver education, child sex. Also considered potential confounding by HOME, maternal prenatal marijuana, smoking, or cocaine use, crowding, child life stress, caregiver age, life stress, and psychology, conflict tactics. disruption in caregiver, parity, child age.	Concurrent Mean (SD): 5.4 (3.3) Interval analyzed: 2.3-9.5 = 10th-90th percentiles	Perseverative errors, WCST Age 7.5 yr	-0.49, p >0.05[e]
Cho et al. (2010)	667 children ages 8-11 yr, born 1997-2000, 5 Korean cities **Cross-sectional**. School-based recruitment, moderate participation rate. Log linear regression model adjusted for age, sex, parental education, maternal IQ, child IQ, birth weight, urinary cotinine. Did not consider potential confounding by parental caregiving quality.	Concurrent Mean (SD): 1.9 (0.67) Interval analyzed: 1.2-2.8 = 10th-90th percentiles	Color-word score Stroop test Ages 8-11 yr	0 (-0.09, 0.08)

Note: Results are presented first for prospective studies then for cross-sectional studies. Within each category, results are presented in order to strength of study design.

WCST = Wisconsin Card Sorting Test, CANTAB = Cambridge Neuropsychological Testing Automated Battery.

[a]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level or 1 µg/g in tooth Pb level in the 10th-90th percentile interval.

[b]The direction of the effect estimate was changed such that a negative estimate represents poorer performance.

[c]95% CI: was constructed using a standard error that was estimated from the reported p-value.

[d]Effect estimates compare test performance of children in higher blood Pb groups to children in lowest blood Pb group.

[e]Sufficient data were not provided to calculate 95% CI.

Results from the Rochester cohort at ages 4 and 5 years indicated associations of concurrent and lifetime average blood Pb level with lower inhibition efficiency in the Shape School task (i.e., giving correct responses and withholding incorrect responses) (Canfield et al., 2003b), poorer problem solving on a spatial planning task (Canfield et al., 2004), and poorer rule learning and reversal (Froehlich et al., 2007). Associations with Shape School tasks were attenuated and lost precision with adjustment for attention ratings, color/shape knowledge, and child IQ. These results suggest that the effect of Pb exposure on executive function may be mediated through effects on knowledge. Froehlich et al. (2007) found a larger concurrent blood Pb-associated decrement in a rule learning and reversal task in the Intra-Extra Dimensional Set Shift in children with the DRD4 exon III 7-repeat microsatellite (assessed using a blood Pb-DRD4-7 interaction term, p = 0.042). While this evidence for effect modification is based on a smaller subset

of subjects (n = 34/174), they add support for Pb-associated decreases in executive function because dopamine is a key neurotransmitter that regulates executive function, the DRD4-7 variant is associated with reduced dopamine-induced signaling in downstream pathways (e.g., cyclic AMP), and the DRD4-7 variant was associated with poorer executive function in this cohort. The association of concurrent blood Pb level with impaired rule learning and reversal also was greater in boys, who had lower mean scores than girls.

In addition to assessment of earlier or cumulative Pb biomarkers, a strength of the prospective studies was the consideration for numerous potential confounding factors. The potential confounding factors varied among studies based on their association with executive function and/or influence on the Pb-executive function relationship. Some prospective studies demonstrated Pb-associated decrements in executive function with adjustment for SES, maternal IQ, and HOME score (Canfield et al., 2004; Stiles and Bellinger, 1993). Others considered and excluded potential confounding by HOME score, parental smoking, maternal education, or birth outcomes (Table 5-8).

The prospective studies indicated blood Pb-associated decrements in executive function in populations with a mean lifetime average blood Pb level of 7.2 µg/dL and a mean concurrent blood Pb level of 6.5 µg/dL. Associations in populations with lower mean blood Pb levels (2-5 µg/dL), as assessed in cross-sectional studies with concurrent blood Pb level, were not as clearly demonstrated. While these studies adjusted for SES and parental cognitive function, most did not examine potential confounding by parental caregiving quality, i.e., HOME score. Among children in New England ages 6-10 years with mean concurrent blood Pb level 2.2 (SD: 1.6) µg/dL, Pb-associated decrements in executive function assessed by WCST, Trail-making, and Verbal cancellation tests were observed primarily in the group with blood Pb levels 5-10 µg/dL. In this study, higher blood Pb level was not associated with poorer color-word score in the Stroop test. Cho et al. (2010) did not find a Pb-associated lower color-word score among children in five Korean cities ages 8-11 years with mean concurrent blood Pb level 1.9 (SD: 0.7) µg/dL. Other studies found associations in children with mean blood Pb levels 2-5 µg/dL but had limited implications because of lack of representativeness of a population with high prevalence of prenatal alcohol exposure (Chiodo et al., 2004) or lack of consideration for potential confounding (Nelson and Espy, 2009).

The associations observed in children between blood or tooth Pb levels and poorer executive function as assessed by the rule learning and reversal components of the Intra-Extra Dimensional Set Shift, Stroop Test, and WCST are supported by observations in animals of Pb-induced impairment in analogous measures of cognitive flexibility, tested with discrimination reversal learning and concurrent random interval (RI-RI) scheduling.

In animals, some of these observations were made with Pb exposures relevant to humans. These tests of cognitive flexibility measure the ability of humans and animals to adjust their responses in reaction to changes in reinforcement. Poorer performance in both children and animals is indicated by increased response errors, decreased percent correct responses, and perseverative responding (e.g., persistence in making a previously-rewarded response after a new shift in reinforcement). As reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b), several lines of evidence indicated Pb-induced impairments in executive function in animals. Lifetime dietary Pb exposures beginning at birth or after weaning that produced peak blood Pb levels of 19-36 µg/dL were found to induce poorer performance on discrimination reversal learning tasks in monkeys ages 5-10 years (Rice and Gilbert, 1990b; Gilbert and Rice, 1987). Recent work has shown that discrimination reversal learning involves NMDA receptors and dopamine-like receptors (Herold, 2010), which are two well-characterized targets of Pb. Gestational Pb exposure (blood Pb of dams >40 µg/dL) was found to impair cognitive flexibility in squirrel monkeys, ages 5-6 years, as indicated by a slower shift or lack of a shift to the lever reinforced more frequently under RI-RI scheduling (Newland et al., 1994). Rats also showed Pb-induced impairments on discrimination reversal tasks, but the authors attributed the changes to learning-related problems instead of impaired executive function (Garavan et al., 2000; Hilson and Strupp, 1997).

5.3.2.5 Academic Performance and Achievement in Children

As described in preceding sections, a large body of evidence demonstrates Pb-associated decrements in FSIQ, with more variable findings for performance on tests of learning and memory. Lower FSIQ and learning are linked with poorer academic performance and achievement, which may have important implications for success later in life. Further, academic performance may better assess the knowledge of an individual in the actual subject areas studied, whereas aptitude tests are used to predict future performance. In addition to FSIQ, the 2006 Pb AQCD described associations between blood Pb levels in children ages 5-18 years and poorer performance on tests of math and reading skills, vocabulary, and spelling, objective measures such as high school completion and class rank, and teacher ratings of academic functioning. Associations continued to be reported in recent studies, including prospective studies examining performance on academic achievement tests and an additional analysis of adolescents participating in NHANES (Table 5-9). Findings from other recent studies had weaker implications because of the lack of representativeness of populations with high prevalence of prenatal alcohol or drug exposure (Min et al., 2009; Chiodo et al., 2007). Multiple testing was common in studies; however, the consistent pattern of blood Pb-associated decrements in academic

performance across the various tests conducted increases confidence that the evidence is not unduly biased by a higher probability of associations found by chance alone.

Key evidence supporting associations between blood Pb level and performance on tests of quantitative, reading, vocabulary, and spelling skills was provided by previous prospective studies in the Boston and Cincinnati cohorts (Ris et al., 2004; Bellinger et al., 1991). Associations with earlier childhood blood Pb levels better characterized the temporal sequence between Pb exposure and poorer academic performance. Evidence from prospective studies did not strongly indicate selection bias with recruitment of participants before or at birth, moderate to high follow-up participation, and in most cases follow-up not biased to higher blood Pb levels and lower cognitive function (Table 5-9). An additional strength of the prospective studies was the consideration of several potential confounding factors (Table 5-9), including birth outcomes, exposure to smoking and drugs, and nutritional status and the adjustment for SES, parental education and IQ, and HOME score. Evidence for associations between blood Pb levels and reading, math, and vocabulary skills provides coherence for the associations observed between blood Pb levels and FSIQ, which includes components of quantitative reasoning and language ability.

			Tooth Pb	Girls: 2.2 (1.1, 4.2) Boys: 1.2 (0.7, 2.2)

Note: Results are organized by method of outcome assessment then by prospective or cross-sectional design. Within each category, results are presented in order to strength of study design.

KABC = Kaufman Assessment Battery for Children, WRAT = Wide Range Achievement Test, WISC = Wechsler Intelligence Scale for Children, BTQ = Boston Teacher's Questionnaire, WIAT = Wechsler Individual Achievement Test, PPVT = Peabody Picture Vocabulary Test, WRAML = Wide Range Assessment of Memory and Learning, WJTA = Woodcock Johnson-III Tests of Achievement.

[a]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level in the interval from the 10th percentile of blood Pb level to the 90th percentile or 10 µg/dL, whichever is lower.

[b]Sufficient data were not provided to calculate 95% CI.

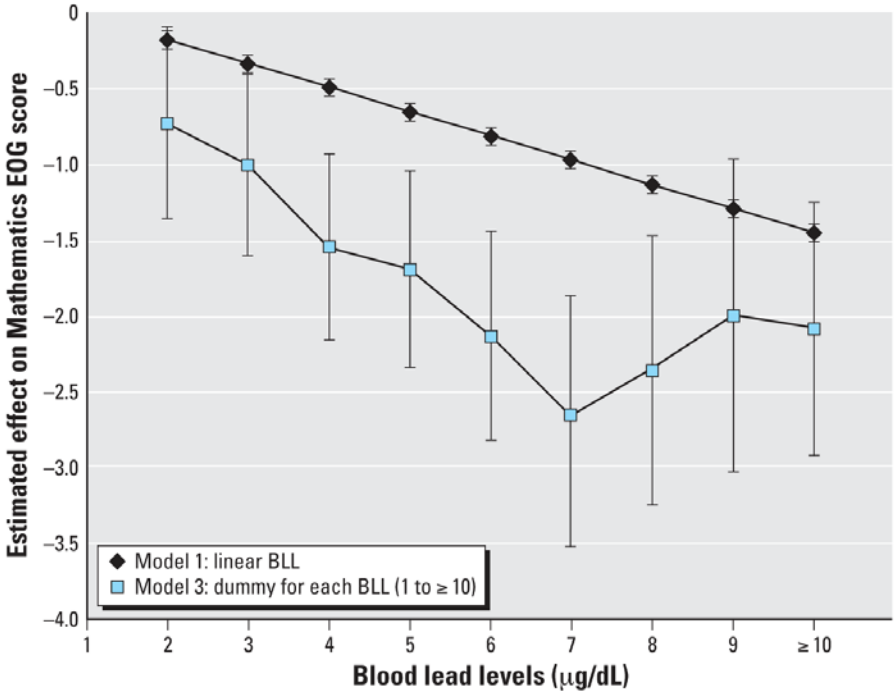
[c]95% CI: was constructed using a standard error that was estimated from the reported p-value.

[d]Effect estimates compare test performance of children in higher blood Pb groups to children in lowest blood Pb group.

The ages at which associations between blood Pb level and performance on academic achievement tests were found varied between prospective studies. In the Boston cohort with lower blood Pb levels (mean: 7.0 µg/dL), a 1 µg/dL increase in age 2 year blood Pb level was associated with a -0.30-point (95% CI: -0.65, 0.05) change in quantitative skills score age at 5 years in the blood Pb interval 1.8-10 µg/dL (Bellinger et al., 1991) with adjustment for SES, maternal IQ and marital status, preschool attendance, HOME, out of home care, residence changes, medication use in previous 12 months, number of adults in home, child sex, race, birth weight, and birth order. Evidence did not strongly indicate an association with verbal skills. In the Cincinnati cohort with higher blood Pb levels, age 6.5 year blood Pb level was associated with decrements in academic performance at ages 15-17 years and 5 years (Ris et al., 2004; Dietrich et al., 1992) but not 4 years (Dietrich et al., 1991). These differences within the Cincinnati cohort could be attributed to changes in blood Pb levels over time or age-related differences in reliability of tests of learning.

Recent prospective studies found associations for earlier childhood blood Pb levels but did not have blood Pb measurements available at other time periods for comparison. The records-based analysis (Miranda et al., 2009; 2007a), multi-factorial nature, or high participation rate of recent studies (Chandramouli et al., 2009) do not indicate a strong influence of selection bias. Miranda et al. (2009; 2007a) linked higher blood Pb levels measured at ages 0-5 years, as ascertained from a surveillance database, with lower end-of-grade (EOG) test scores in 8,600 fourth grade children in seven of the largest counties in North Carolina and then in 57,678 children in the entire state. A strength of the analyses was the availability of individual-level data on a large number of children representative of the North Carolina fourth grade population. The large numbers of children with blood Pb levels 2-5 µg/dL provided greater power to estimate the effects of Pb in the lower range of blood Pb levels. In each analysis, children with an earlier blood Pb level of 2 µg/dL had lower EOG scores ($p \leq 0.05$) compared with children with a blood Pb level of 1 µg/dL. Further, across deciles of blood Pb level, the decrease in EOG score generally was monotonic (Figure 5-6). Because these children were born in the early- to mid-1990s and blood Pb levels were measured earlier in childhood, it is less likely that associations were influenced by higher past Pb exposures.

Due to the records-based study design, investigators had a smaller set of potential confounding factors available than those considered in the prospective studies described above. Results were adjusted for sex, race, school-type, school district, age of blood Pb measurement, parental education, participation in a free or reduced lunch program as a measure of SES, and in the analysis of seven North Carolina counties, daily use of a computer as a measure of a stimulating home environment (Miranda et al., 2007a). While there may be no complete single measure of SES and parental caregiving quality, the covariates examined in these analyses are not as well characterized, and the results may be subject to residual confounding.



Note: These results illustrate the decrease from a baseline math end-of-grade (EOG) score of 262.6 for a hypothetical referent white female, screened at 2 years of age, living in Wake County, NC, with parents with a high school education, not enrolled in the school lunch program, and who does not use a computer every day (i.e., model covariates = zero). Results from modeling blood Pb level as a continuous variable (linear, black diamonds) or categorical variable (dummy, blue squares) indicate decreasing EOG score with increasing blood Pb level.

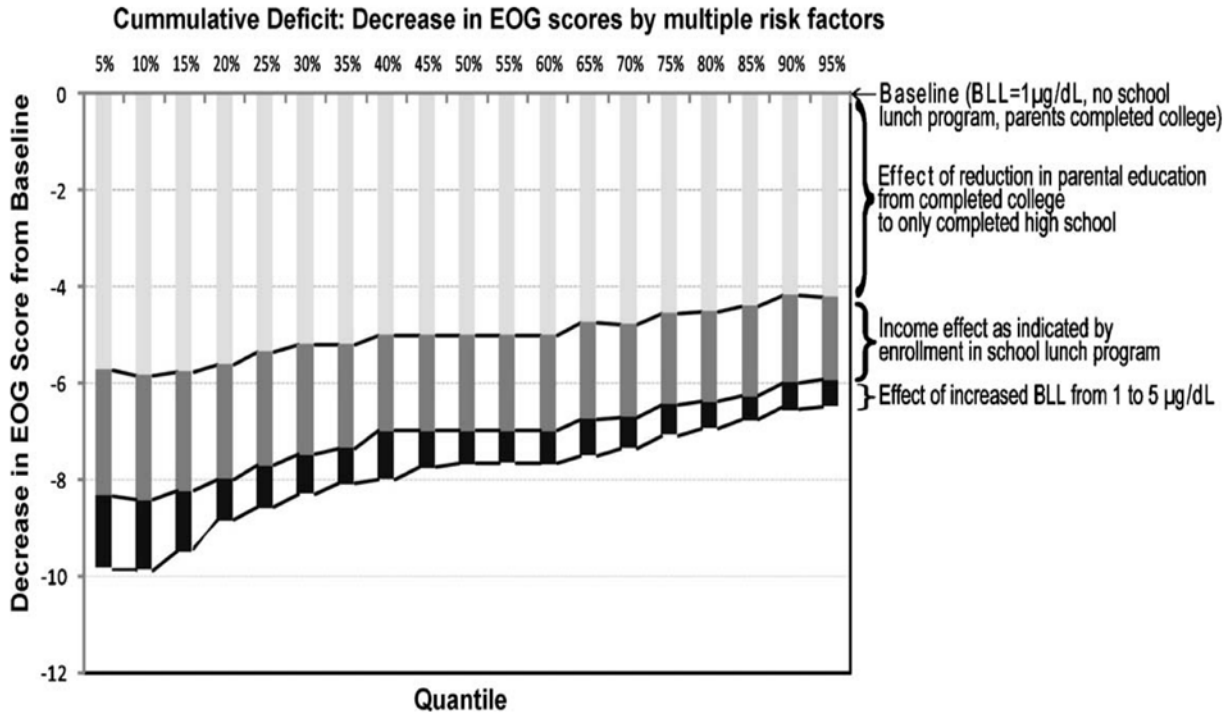
Figure 5-6 Associations between childhood blood Pb levels and fourth grade End-of-Grade (EOG) math scores.

In the statewide dataset, compared with children with an earlier (between ages 9 and 36 months) blood Pb level of 1 µg/dL, children with an earlier blood Pb level of 2 µg/dL had a 0.30-point lower (95% CI: -0.58, -0.01) reading EOG score (Miranda et al., 2009). While the linear regression analyses indicated fractional-point effect estimates, quantile regression indicated differential effects across the EOG distribution (Figure 5-7). Compared with linear regression, quantile regression is more robust in response to outliers and can identify whether effects differ at the top and bottom tails of the outcome distribution rather than at the mean. With increasing blood Pb level, there was a greater decrease in EOG in lower tail of the EOG distribution than in the middle or upper portions of the distribution (e.g., leftmost black bar versus rightmost black bar, Figure 5-7). For example, an increase in blood Pb level from 1 to 10 µg/dL was associated with a 2.3-point decrease in EOG score in children in the 5th percentile of EOG and a 0.8-point decrease in children in the 95th percentile of EOG score. These findings indicated that children with the lowest EOG performance may be more affected by Pb exposure. Using quantile regression, Miranda et al. (2009) also showed that while cumulative social

risk (lower parental education, enrollment in a school lunch program) had a greater magnitude of negative association with EOG score, blood Pb level was independently associated with EOG score decrements that were as large as 1 to 2 points.



Note: Baseline score calculated for a hypothetical referent individual with a blood Pb level of 1 µg/dL, parents completed college, and not enrolled in the school lunch program (i.e., model covariates = zero). Vertical bars indicate the decrease in EOG score associated with blood Pb level and covariates in various percentiles of EOG score (lowest to highest, left to right). An increase in earlier childhood blood Pb level is associated with a larger decrease in EOG score (larger black bars on left) among children in the 5th and 10th percentiles of EOG score than children in the 90th and 95th percentiles (smaller black bars on right).

Figure 5-7 Greater reduction in End-of-Grade (EOG) scores with increasing blood Pb level in lower percentiles of the test score distribution.

Similar to Miranda et al. (2009), Chandramouli et al. (2009) found associations between earlier childhood blood Pb levels (age 30 months) and later academic performance (Standard Assessment Test [SAT] at age 7 years). In this study of 488 children in the U.K., who had similar sociodemographic characteristics as those found in the U.K. census, a doubling of age 30 month blood Pb level was associated with a 0.3-point (95% CI: 0.1, 0.5) decline in SAT grade. Results were adjusted for maternal education and smoking, home ownership, parental SES and several factors related to caregiving quality including home facilities score, family adversity index, and parenting attitudes. In analyses of blood Pb level categories, lower SAT scores were most clearly indicated in

children with age 30 month blood Pb levels >5 µg/dL. Children with blood Pb levels 2-5 µg/dL generally did not have lower SAT scores than children with blood Pb levels 0-2 µg/dL.

Consistent with prospective studies, cross-sectional studies found associations between higher concurrent blood Pb level and lower scores on tests of math and reading, including large studies of children participating in NHANES. While cross-sectional studies considered potential confounding by SES and caregiver education, few considered parental cognitive function, and none considered parental caregiving quality. Lanphear et al (2000) and Krieg et al. (2010) found concurrent blood Pb-associated decrements in math and reading score among 4,852 children ages 6-16 years and 766-780 children ages 12-16, respectively, participating in NHANES. The examination of multiple exposures and outcomes in NHANES increases confidence that associations are not unduly influenced by selection bias. While the mean blood Pb levels were low in these study populations, ~2 µg/dL, the influence of higher past Pb exposures on findings cannot be excluded. Consistent with studies of FSIQ, Lanphear et al. (2000) found a supralinear concentration-response relationship. A 1 µg/dL increase in concurrent blood Pb level was associated with a change in reading score of -0.70-points (95% CI: -1.0, -0.37) among all subjects and -1.1-points (95% CI: -1.54, -0.58) among the 4, 043 children with blood Pb levels <5 µg/dL. A supralinear concentration-response relationship also was found in children ages 7 years in Mexico living near a metal foundry as indicated by larger blood Pb-associated decrements in math and vocabulary scores among children with concurrent blood Pb levels <10 µg/dL (Kordas et al., 2006). In contrast with these findings, among children ages 6-10 years in New England decrements in reading and math scores were found in association with higher blood Pb levels, i.e., blood Pb levels 5-10 µg/dL compared with blood Pb levels 0-2 µg/dL (Surkan et al., 2007).

Prospective studies in a Boston, MA area cohort and New Zealand cohort found associations of tooth Pb levels measured at an earlier age (ages 6-8 years) with school performance ascertained at ages 16-18 years from school records (Fergusson et al., 1997, 1993; Needleman et al., 1990), suggesting the effect of early exposure to Pb may be persistent. In the New Zealand cohort at ages 12-13 and 18 years, recruitment rate and follow-up participation were high, and model correction for nonrandom sample attrition produced robust results, indicating lack of undue selection bias (Fergusson et al., 1997, 1993). Further, associations observed at ages 12-13 years between higher tooth Pb level and lower teacher ratings of math, reading, and writing abilities (Fergusson et al., 1993), which are subject to greater measurement error, were supported by associations observed at age 18 years with more objective measures such as lower probability of completion of high school and lower scores on school exams (Fergusson et al., 1997). In this cohort, Pb-associated decrements in school performance were found with consideration for

potential confounding by several factors including SES, parental education, HOME score, sex, ethnicity, number of school changes, perinatal history, breastfeeding, maternal age, and residence in weatherboard housing and near busy roads.

In one Boston-area cohort, age 6-8 years tooth Pb level >20 µg/g was associated with dropping out of high school at age 18 years with an odds ratio of 7.4 (95% CI: 1.4, 40.7) (Needleman et al., 1990). The relatively small sample size (n = 132) and adjustment for several potential confounding factors, including maternal education, IQ, and age, SES, and subject alcohol use may have contributed to the imprecision of the effect estimate. Parental caregiving quality was not considered. Participation was biased to children with lower tooth Pb levels and higher SES. This selection bias likely did not produce a spurious association; however, the results may be less generalizable to the original study population. In another Boston-area cohort, higher tooth Pb level at age 6 years was associated with higher teacher ratings of age 8 year spelling and reading difficulties in girls but not boys (Leviton et al., 1993). Despite the large sample size (n = 1923) and high follow-up participation, the study did adjust for SES or parental caregiving quality. However, other unspecified potential confounding factors were considered.

5.3.2.6 Integrated Summary of Cognitive Function in Children

Results from recent epidemiologic and animal studies add to the strong evidence base reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) demonstrating that Pb exposure is associated with decrements in cognitive function in children, based on associations observed with FSIQ, and also executive function, and academic performance. Associations with performance on tests of learning and memory were less consistently found (Table 5-5). A large epidemiologic evidence base demonstrates associations of higher blood Pb level with lower FSIQ in school-aged children (Figure 5-2 and Table 5-3), with smaller bodies of evidence indicating associations with lower scores on tests of executive function, and academic performance in children ages 4 to 18 years (Table 5-8 and Table 5-9). There was no clear indication that blood Pb level was more strongly associated with performance in a particular domain of cognitive function. The Pb-associated decrements in cognitive function observed in children were strongly supported by observations in animals of decrements in learning, memory, and executive function with relevant dietary Pb exposures. In particular, coherence was found between observations of Pb-associated decrements in performance on spatial span tasks in children and Morris water maze in animals both of which test visual spatial memory on spatial working memory tasks in children and the radial arm maze in animals (Section 5.3.2.3). Coherence also was found with Pb-associated changes in performance on tests of rule learning and reversal in humans and animals (Section 5.3.2.4) both of

which assess cognitive flexibility. Additional biological plausibility for Pb-associated cognitive function decrements was provided by toxicological evidence for the effects of Pb on neurophysiological and neurochemical processes that mediate cognition.

Compelling epidemiologic evidence for Pb-associated cognitive function decrements was described in the 2006 Pb AQCD (U.S. EPA, 2006b) for FSIQ (see Section 5.3.2.1 of this ISA also). Across studies, FSIQ was measured with similar instruments (i.e., WISC-R, WISC-III, WPPSI, Stanford-Binet) scored on a similar scale with similar measurement error. Associations were found in most of the prospective studies, conducted in the U.S., Mexico, Europe, and Australia, in representative populations with high follow-up participation without indication of selective participation among children with higher blood Pb levels and lower cognitive function (Figure 5-2 and Table 5-3) that could produce spurious associations. The prospective studies found associations of blood Pb levels measured concurrently with FSIQ (ages 4-17 years) and earlier in life (i.e., prenatal cord or maternal, age 2 year) or averaged over multiple years, better establishing the temporal sequence between Pb exposure and cognitive function decrements than cross-sectional studies. multiple testing was common; however, the consistent pattern of association observed across the ages of blood Pb level and/or cognitive test examined in most previous and recent studies increases confidence that the evidence is not unduly biased by a higher probability of associations found by chance alone. Another strength of the prospective evidence was the consideration of several potential confounding factors. As indicated in Table 5-3, results from most cohorts were adjusted for maternal IQ and education, child sex and birth weight, SES, and HOME score. Although not considered as frequently, some studies also indicated lack of confounding by parental smoking, birth order, and nutritional status. The robustness of the blood Pb-FSIQ association in children was substantiated in a pooled analysis of seven prospective studies by Lanphear et al. (2005) as well as multiple meta-analyses that combined results across various prospective and cross-sectional studies (Pocock et al., 1994; Schwartz, 1994; Needleman and Gatsonis, 1990), with Schwartz (1994) demonstrating the robustness of evidence to potential publication bias.

Comparisons of effect estimates across studies are difficult because of the variability in population blood Pb distributions, lifestage of blood Pb level examined, type of model examined (linear versus nonlinear), and tests conducted. The pooled analysis of seven prospective cohorts demonstrated precision of effect estimates by finding a relatively narrow range of effect estimates, -2.36 to -2.94 points per natural log increase in blood Pb level, excluding one study at a time (Lanphear et al., 2005). In a linear model, a greater decrease in FSIQ estimated for a 1 µg/dL increase in concurrent blood Pb for the 244 children who had peak blood Pb levels <10 µg/dL (-0.80 points [95% CI: -1.74, -0.14]) and the 103 children with peak blood Pb levels <7.5 µg/dL (-2.9 points [95% CI: -5.2,

-0.71]). Among children with peak blood Pb levels <10 µg/dL and <7.5 µg/dL, the median concurrent blood Pb levels were 4.2 µg/dL and 3.2 µg/dL, respectively (Hornung, 2008). Among individual studies, a wide range of effect estimates was reported. However, studies varied in model specification and the blood Pb level range examined. Similarly large effects were estimated in the Boston and Rochester cohorts, which differed widely in racial and SES distributions (Canfield et al., 2003a; Bellinger et al., 1992). While the sample sizes were smaller, these studies had least as extensive consideration for potential confounding as other studies. Further, each study estimated larger effects for children whose peak blood Pb levels never exceeded 10 µg/dL, -1.8 points (95% CI: -3.0, -0.60) per 1 µg/dL increase in concurrent blood Pb level in the Rochester cohort (n = 101, 59%) (Canfield et al., 2003a) and -1.6 points (95% CI: -2.9, -0.2) per 1 µg/dL in age 2-year blood Pb level in the Boston cohort (n = 48, 32%) (Bellinger and Needleman, 2003). These subsets of children had mean blood Pb levels of 3.3 (Rochester) and 3.8 µg/dL (Boston). Some recent cross-sectional studies estimated smaller effects but with examination of populations with higher concurrent blood Pb levels (means: 7, 8.7 µg/dL) using a linear model (Kordas et al., 2011; Min et al., 2009). Other recent studies estimated similar effects as previous studies although the log-linear models make comparisons difficult. Among children ages 3-7 years in India, a 1 µg/dL increase in concurrent blood Pb level was associated with a 1.2-point decrease (95% CI: -1.9, -0.37) in FSIQ from the 10th percentile of blood Pb level 5.8 to 10 µg/dL (Roy et al., 2011). Kim et al. (2009b) found that a 1 µg/dL increase in concurrent blood Pb level was associated with a 3.2-point decrease (95% CI: -6.1, -0.23) in FSIQ among children ages 8-11 years in Korea with blood Mn levels >1.4 µg/dL in the 10th-90th percentile interval of blood Pb level (0.9-2.8 µg/dL). In this study, the potential influence of higher past Pb exposures cannot be excluded. Further, while these recent studies adjusted for parental education and SES, parental caregiving quality was not examined. The relatively low blood Pb levels in the Rochester and Boston cohorts, consideration of peak blood Pb levels, and the adjustment for several potential confounding factors indicate that their results may be more representative.

Previous prospective studies, several of which contributed to the FSIQ evidence, provided key evidence for associations of blood or tooth Pb level with decrements in executive function and academic performance for the reasons described for FSIQ. Endpoints associated with blood or tooth Pb level included rule learning and reversal, reading and math skills assessed using neuropsychological tests and school performance assessed from school records. Higher concurrent blood Pb level was associated with lower scores on tests of math and reading in the large study of children participating in NHANES (Lanphear et al., 2000). Recent studies conducted in the U.S., Mexico, Europe, and Asia, most of which were cross-sectional, also found associations between higher blood Pb level and lower cognitive function. The few recent prospective studies indicated

associations between higher earlier childhood blood Pb level, ages 9-36 month and age 30 months, respectively, with poorer academic performance in children in North Carolina at age 9 years (Miranda et al., 2009) and in children ages 7 years in the U.K. (Chandramouli et al., 2009).

In most studies that provided unadjusted and adjusted effect estimates, blood Pb level was associated with a smaller but statistically significant decrement in FSIQ after adjusting for potential confounding factors (Palaniappan et al., 2011; Kim et al., 2009b; Lanphear et al., 2005; Canfield et al., 2003a). The consideration for potential confounding varied among studies. Most studies adjusted for SES-related variables such as the Hollingshead Index, household income, and/or parental education. Several, in particular the prospective studies, adjusted for parental cognitive function and parental caregiving quality commonly evaluated as HOME score. Overall, recent studies considered potential confounding by SES and parental IQ or education but not parental caregiving quality. Analyses of associations between potential confounding factors and blood Pb level and cognitive function indicated that the confounding factors may vary across populations and endpoints. In the Cleveland cohort, adjustment for HOME score attenuated the blood or tooth Pb level-cognitive function relationships (Greene and Ernhart, 1993; Greene et al., 1992; Ernhart et al., 1988). In the Rochester cohort, HOME score met the criteria for adjustment in models for FSIQ (Canfield et al., 2003a) but not all measures of memory and executive function (Froehlich et al., 2007; Canfield et al., 2004; 2003b). Adjustment for SES is difficult as it is highly correlated with Pb exposure and there is no single measure that represents SES. Residual confounding also is likely by factors not considered. The combination of evidence from prospective studies that considered several well-characterized potential confounding factors plus evidence that Pb exposure induces impairments in cognitive function in animals, in particular, spatial memory and executive function, which are associated with blood or tooth Pb levels in children increases confidence that the associations between blood and tooth Pb levels and cognitive function observed in children represent a relationship with Pb exposure.

With regard to important lifestages and durations of Pb exposure, toxicological evidence clearly demonstrates impaired learning and memory in animals exposed to Pb gestationally with or without early postnatal exposure. Impairments in learning and memory observed with lower blood Pb levels (8-17 µg/dL) were found with Pb exposures that began during the gestational or lactation period. The effect of early life Pb exposures is supported by evidence that processes such as neurogenesis and synaptic pruning are highly active during the first few years of life (Rice and Barone, 2000; Landrigan et al., 1999). However, evidence in a group of monkeys also indicates impaired learning with Pb exposure beginning later during the juvenile period, indicating that Pb exposure in infancy is not necessary to induce impairments in cognitive function (Rice, 1992b, 1990;

Rice and Gilbert, 1990b). Epidemiologic studies also point to cognitive function decrements associated with blood Pb levels measured at various lifestages and time periods. Among studies of young children <3 years, several found stronger associations of MDI with prenatal (maternal or cord) blood Pb than with postnatal child blood Pb (Hu et al., 2006; Bellinger et al., 1987; Dietrich et al., 1987a; Vimpani et al., 1985). However, in older children, ages 4-17 years, in whom cognitive function is more stable and reliably measured, decrements in cognitive function were associated with more strongly with indicators of postnatal Pb exposure, i.e., concurrent, early childhood, and cumulative average blood Pb levels as well with tooth Pb levels. Evidence did not clearly identify an individual critical postnatal time period or duration of Pb exposure in terms of risk of developing cognitive function decrements. Because of the contribution of bone Pb levels to concurrent blood Pb levels in children, associations with concurrent blood Pb levels may reflect an effect of past and recent Pb exposures.

Previous prospective studies found blood Pb-associated decrements in cognitive function in populations with mean blood Pb levels 5-10 µg/dL (Table 5-3). In analyses restricted to children in the lower range of the blood Pb distribution (e.g., <10 µg/dL), associations with FSIQ were found in groups of children with mean age 2 year or concurrent blood Pb levels 3-4 µg/dL with consideration of peak blood Pb levels (Bellinger, 2008; Canfield, 2008; Hornung, 2008). Several recent studies found associations of FSIQ with lower blood Pb levels (primarily concurrent), population means 2-5 µg/dL, (Kim et al., 2009b; Jusko et al., 2008; Zailina et al., 2008; Chiodo et al., 2007) for FSIQ but not consistently for other indices of cognitive function (Cho et al., 2010; Miranda et al., 2010; Chandramouli et al., 2009; Surkan et al., 2007). Many of these recent studies had uncertainties related to the influence of higher past Pb exposures, high prevalence of prenatal drug exposure, or potential confounding. Several recent toxicological studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels, 8-17 µg/dL (Cory-Slechta et al., 2010; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007). Recent evidence from the Cory-Slechta laboratory found learning impairments with lower lifetime Pb exposures when combined with stress, which potentially may be mediated via effects on corticosterone and dopamine (Rossi-George et al., 2011; Cory-Slechta et al., 2010; Rossi-George et al., 2009; Virgolini et al., 2008a).

The biological plausibility for epidemiologic and toxicological evidence linking Pb exposure to decrements in cognitive function is provided by the well-characterized toxicological evidence for Pb exposure interfering with development of the brain and activity of neurochemical processes that mediate cognitive function (Section 5.3.11). Pb has been shown to increase the permeability of the blood-brain barrier and deposit in the CNS. Pb has been shown to impair neurogenesis, synaptic architecture, and neurite outgrowth. Cognitive function is mediated by the cortical and subcortical structures of the

brain that integrate function in the hippocampus, prefrontal cortex, and nucleus accumbens using dopamine and glutamate as primary neurotransmitters. Experimental studies have shown that Pb induces changes in dopamine and glutamate release in these regions and decreases long-term potentiation, which is a major cellular mechanism underlying synaptic plasticity and learning and memory.

5.3.2.7 Epidemiologic Studies of Cognitive Function in Adults

Adults without Occupational Pb Exposures

As described in the preceding section, Pb exposure that begins in gestation and lasts through the early postnatal period or for a lifetime or begins after infancy has been shown to induce learning impairments in adult animals. Less well characterized are learning impairments in adult animals due to adult-only Pb exposures. As reported in the 2006 Pb AQCD, epidemiologic studies have examined cognitive performance in adults without occupational Pb exposure primarily in association with concurrently measured blood and bone Pb levels and have found associations with bone Pb levels but not blood Pb levels (U.S. EPA, 2006b). Recent studies produced similar findings and provided new evidence from prospective analyses (Table 5-10).

Evidence was provided by large cohorts examining multiple exposures and outcomes, reducing the likelihood of selective participation of subjects with higher Pb exposures and cognitive deficits. Most studies performed multiple tests of cognitive function. However, associations with bone Pb level were not isolated to a few tests. Several publications are available; however, many are variant analyses in the same population (e.g., Normative Aging Study [NAS], NHANES) and are not considered as all independent assessments of the Pb-cognitive function relationship. Further, although evidence is available from longitudinal cohorts, most analyses are cross-sectional examining the association between one measurement of cognitive function and a concurrent measure of blood or bone Pb level. Because temporality cannot be determined, causal inference regarding the effects of Pb exposure is limited. In analyses of bone Pb level, this limitation is mitigated somewhat because bone Pb level reflects several years of exposure. Additionally, with blood and bone Pb level, it is difficult to characterize the specific timing, duration, frequency, and level of Pb exposure that contributed to associations observed with cognitive function. This uncertainty may apply particularly to assessments of blood Pb levels, which in nonoccupationally-exposed adults, reflect both current exposures and cumulative Pb stores in bone that are mobilized during bone remodeling (Sections 4.3 and 4.7.3). Although studies adjusted for age, a common limitation is the potential for residual confounding by age because of the strong

correlation between increasing bone Pb levels and increasing age. However, the coherence with evidence for cognitive function decrements associated with long-term Pb exposure in animals provides support for associations observed in adults. Because of the difficulty in establishing the temporal sequence between Pb exposure and cognitive function in cross-sectional studies, in the review of evidence, emphasis was placed on prospective analyses. Emphasis also was placed on studies that considered several potential confounding factors such as age, education, SES, smoking, and alcohol use.

Evidence from Prospective Studies

Key evidence for the effects of Pb exposure on cognitive function of adults has been provided by recent prospective analyses of the large Baltimore Memory Study (BMS) and NAS. Strengths of these studies include comparisons of associations between bone and blood Pb levels, the repeated assessment of Pb biomarker levels and cognitive performance, the high follow-up participation of subjects, and lack of selective attrition by Pb biomarker levels and demographic characteristics. In particular, the repeated assessments permitted the examination of associations of bone Pb levels with changes in cognitive function over time, which better established the temporal sequence between Pb exposure and subsequent changes in cognitive function. The BMS and NAS differed in many respects, including sex and race of subjects, the test instruments used, and potential confounding factors considered. The BMS included men and women, 50-70 years of age, residing in Baltimore, MD. A total of 1,140 out of 2,351 (48.5%) subjects participated from neighborhoods that represented a diversity of race and SES. This study was unique in that it included a large proportion of African-Americans (n=395). In comparison, the NAS involved only men (original n = 2,280) residing in the Greater Boston area. Subjects primarily were white and at enrollment were ages 21 to 80 years and had no current or past chronic medical conditions. Both studies adjusted for age and education. The BMS additionally adjusted for household wealth, and the NAS additionally adjusted for smoking and alcohol intake. Results from both of these cohorts with different demographics and methodology indicated Pb-associated cognitive function decrements.

In the BMS, longitudinal analyses involved repeat cognitive testing at 14-month intervals. Most subjects completed follow-up; 91% at the second round of testing and 83% at the third round (Bandeen-Roche et al., 2009). An interquartile range higher baseline tibia Pb level (12.7 μg/g) was associated with a 0.019 unit (95% CI: -0.031, -0.007) per year decrease in eye-hand coordination z-score, with adjustment for age, sex, race, SES, and interviewer, with a larger decrease estimated for African Americans than for whites (Table 5-10). Results were not homogeneous across the various tests performed. Tibia Pb levels were more weakly associated with time-related decreases in language, processing speed, and executive function; however, most effect estimates were

negative in direction. Further, for language and executive function, tibia Pb level was associated with greater decreases in scores among whites than African Americans.

Table 5-10 Associations of blood and bone Pb levels with cognitive function in adults.

Study[a] Population and Methodological Details (Presented first for prospective analyses then for cross sectional analyses. Within categories, studies are presented in order of strength of methodology)	Cognitive Test	Subgroup (where examined)	Blood Pb Effect Estimate (95% CI)	Bone Pb Effect Estimate (95% CI)
Prospective Studies:				
Bandeen-Roche et al. (2009) 943, ages 50-70 yr at baseline, BMS, Baltimore, MD Large sample of men and women of various races/ethnicities with repeated measures of cognitive function and tibia Pb. High follow-up participation over 28 mo. Marginal linear regression models adjusted for age, sex, household wealth, education, race/ethnicity, interviewer. Did not consider potential confounding by history of smoking or alcohol use. Tibia Pb Mean (SD): 19 (12.7) µg/g	**Longitudinal associations**		NOT EXAMINED	**Change in Z-scores per IQR increase:**
	Eye/hand coordination - Purdue pegboard	African-Americans		-0.032 (-0.052, -0.012)/yr
		White		-0.009 (-0.024, 0.006)/yr
	Cross-sectional associations			
	Verbal memory/learning – Rey auditory verbal learning test	African-Americans		0.006 (-0.09, 0.10)
		White		-0.076 (-0.15, 0.001)
	Language – Boston naming test	African-Americans		0.065 (-0.010, 0.14)
		White		-0.024 (-0.12, 0.07)
Weisskopf et al. (2007b) 405-749 males, mean age 68.7 yr at baseline, NAS, Boston, MA area. Large sample, only men, primarily white. Repeated measures of cognitive function and tibia Pb. High follow-up participation over 3.5 yr. Linear repeated measures analysis adjusted for age, age^2, education, smoking status, current alcohol intake, yr between bone Pb measurement and first cognitive test, yr between cognitive tests. Also evaluated language, computer experience, physical activity. Note: Effect estimates in bold indicate the stronger association between blood Pb and bone Pb level. IQR = Interquartile range, BMS = Baltimore Memory Study, NAS = Normative Aging Study, NES2 = Neurobehavioral Evaluation System 2, WISC-R = Wechsler Adult Intelligence Scale-Revised, CERAD = Consortium to Establish Registry for Alzheimer's disease, HFE = Human Hemochromatosis protein, NPH = Neighborhood Psychosocial Hazard, TICS = Telephone Interview for Cognitive Status, EBMT = East Boston Memory Test, CANTAB = Cambridge Neuropsychological Test Automated Battery, CSID = Community Screening Instrument for Dementia, IU = Indiana University.

[a]Studies are presented first for prospective analyses then for cross sectional analyses. Within categories, studies are presented in order of strength of methodology.

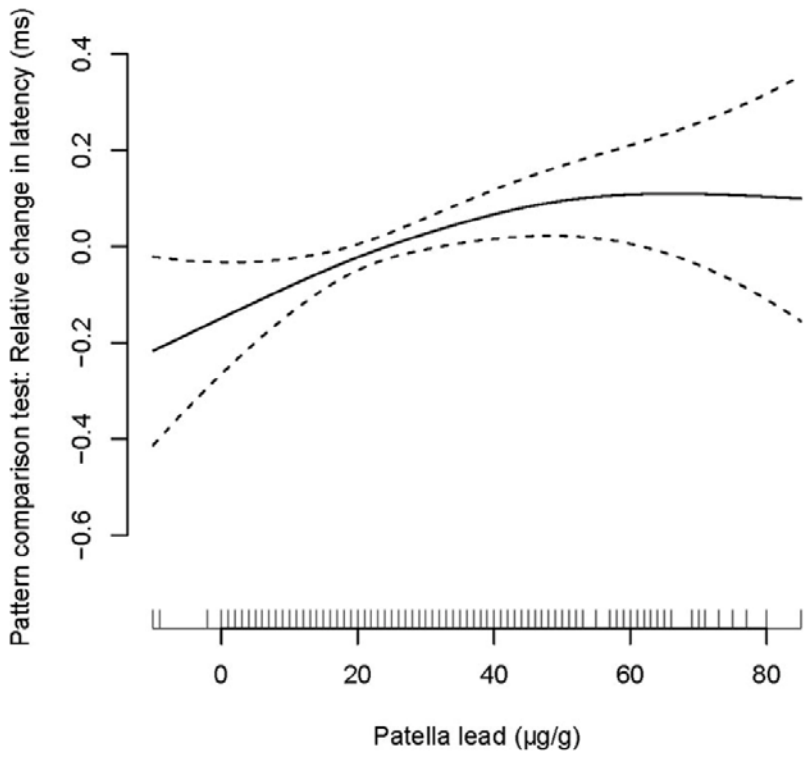
[b]Effect estimates indicate interactions between Pb and category of NPH, with the lowest tertile of NPH serving as the reference group.

[c]Effect estimates indicate interactions between Pb and ALAD genotype.

[d]The directions of effect estimates were changed to indicate a negative slope as a decrease in cognitive performance.

[e]Results refer to mean cognitive function scores among tertiles of bone Pb. Tertile concentrations not reported.

Similar to the BMS, among NAS men, higher baseline tibia Pb levels were associated with decreases in cognitive performance over time in longitudinal analyses with repeated measures of cognitive function plus a bone Pb-time interaction term in order to estimate the association between baseline bone Pb level and decline in cognitive test score over time (Weisskopf et al., 2007b). This NAS analysis expanded the evidence base by also finding associations with patella Pb levels. Two measurements of cognitive function, collected approximately 3.5 years apart were available for 60-70% of participants. Both tibia and patella Pb levels were associated with decrements in executive function, short-term memory, and visuospatial skills (as indicated by increased response latency on a pattern comparison test). The strongest effect was estimated for the latter. Weisskopf et al. (2007b) also found a nonlinear association with patella Pb, with latency times becoming worse over time (i.e., larger values indicating slower response time) up to approximately 60 μg/g patella Pb then leveling off at higher levels (Figure 5-8). A 20 μg/g difference in patella Pb level was associated with an increase in latency of 0.073 ms (95% CI: 0.04, 0.12) among all men and a 0.15 ms increase among men with patella Pb level <60 μg/g. Both patella and tibia Pb were associated with fewer errors on the pattern comparison test. The authors proposed that this may be related to slowing reaction time to improve accuracy. When the nine men with the highest bone Pb levels were removed, the association with fewer errors was no longer statistically significant. However, the authors did not indicate whether the point estimate changed.



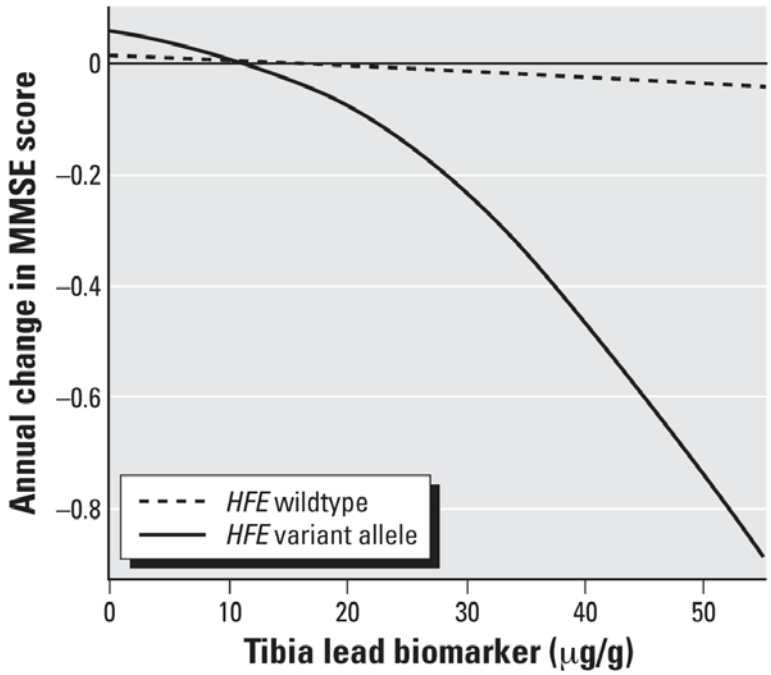
Note: Models are adjusted for age, age squared, education, smoking, alcohol intake, years between bone Pb measurement and first cognitive test, and years between the cognitive tests. The 9 subjects with the highest patella Pb levels (>89 µg/g bone mineral) were removed. The estimated concentration-response is indicated by the solid line and the 95% confidence interval by the dashed lines. The patella Pb level-associated increase in response latency is larger among men with patella Pb levels <60 µg/g. Patella Pb levels of all individual subjects are indicated by short vertical lines on the abscissa. (reference = 0 at mean of patella Pb level).

Source: Reprinted with permission of Williams & Wilkins, Weisskopf et al. (2007b).

Figure 5-8 Nonlinear association between patella Pb level and the relative change over 3.5 years in response latency on the pattern comparison test in men from the Normative Aging Study.

Longitudinal analysis of the NAS cohort also indicated that hemochromatosis (HFE) gene variants modified the blood Pb-cognition association (Wang et al., 2007a). In models adjusted for age, years of education, smoking status, pack-years smoking, nondrinker, grams/day alcohol consumption, English as first language, computer experience, and diabetes, an interquartile range higher tibia Pb level (15 µg/g) was associated with a 0.22 point steeper annual decline (95% CI: -0.39, -0.05) in Mini-Mental State Examination score (MMSE, which assesses cognitive impairment in a number of domains) among the 130 (36%) men with either the H63D or C282Y variant. The association was found to be nonlinear, with larger Pb-associated declines observed at higher tibia Pb levels (Figure 5-9, solid line). The change in MMSE score associated with 15 µg/g higher tibia Pb levels was comparable to that found between NAS men who were 4 years apart in age. Tibia Pb level was not associated with a decline in MMSE score in men with the HFE wildtype genotype (Figure 5-9, dashed line). Bone Pb levels did not

differ widely by HFE variant. HFE variants, H63D and C282Y, are associated with hemochromatosis, a disease characterized by higher iron body burden. Iron metabolism has been hypothesized to affect neurodegenerative diseases, which may explain the observed effect modification. However, firm conclusions are not warranted.



Note: The lines indicate curvilinear trends estimated from the penalized spline method. Among hemochromatosis (HFE) wild-types, the association between tibia Pb and annual cognitive decline was nearly null (dashed line). Among variant allele carriers, the association tended to deviate from linearity (solid line, p = 0.08), with a greater tibia Pb-associated decline in MMSE observed among men with higher tibia Pb levels. The model was adjusted for age, years of education, smoking status, pack-years smoking, nondrinker, grams/day alcohol consumption, English as first language, computer experience, and diabetes.

Figure 5-9 Nonlinear association of tibia Pb level with annual rate of cognitive decline, by hemochromatosis genotype in men from the Normative Aging Study.

Evidence from Cross-sectional Studies

Associations between bone Pb levels and decrements in cognitive function in adults also are supported by evidence from several cross-sectional studies conducted in the BMS and NAS cohorts and other populations. The cross-sectional studies have contributed evidence for stronger associations of cognitive function decrements with bone Pb levels than blood Pb level and for associations with adjustment for additional potential

confounding factors such as diet and medication use. While cross-sectional studies examined factors that may potentially increase risk of Pb-associated cognitive function decrements in adults, they each examined different factors and did not produce conclusive evidence. These subgroup analyses also are subject to higher probability of finding an association by chance.

In addition to comparisons of blood and bone Pb levels, cross-sectional analyses of the BMS included detailed analysis of potential confounding, although smoking and alcohol use were not examined. Among 991 adults, both higher concurrent blood and bone Pb level were associated with poorer performance in tests of language, processing speed, eye-hand coordination, executive function, verbal memory and learning, visual memory, and visuoconstruction; however, associations with tibia Pb level tended to be larger in magnitude (Table 5-10) (Shih et al., 2006). Mean (SD) blood and tibia Pb levels were 3.46 (2.23) μg/dL and 18.7 (11.2) μg/g, respectively. Tibia Pb levels were associated with worse performance on tests in all domains with adjustment for age, sex, testing technician, and presence of the apolipoprotein (APO)E-ε4 allele (potential risk factor for Alzheimer's Disease). The magnitudes of associations were attenuated with additional adjustment for education, race, and household wealth; however, in these more fully-adjusted models, higher tibia Pb levels remained associated with poorer performance in all domains except language and processing speed. The strongest association was found for visuoconstruction, which assesses visuospatial skills and motor skills. A 1 μg/g bone higher tibia Pb level was associated with a 0.0044 SD (95% CI: -0.0091, 0.0003) lower visuoconstruction score. Analysis of tibia Pb as a quadratic term did not indicate a nonlinear relationship with visuoconstruction.

In contrast with longitudinal results in BMS, race-stratified analyses of persistent effects in cross-sectional analyses indicated that tibia Pb levels were associated with greater decreases in performance on tests of eye-hand coordination, executive function, and verbal memory and learning among whites than among African Americans (Bandeen-Roche et al., 2009). Among all subjects, tibia Pb-associated decrements in cognitive performance were modified by neighborhood level psychosocial stress. Specifically, higher tibia Pb levels were associated with larger decrements, particularly in language, eye-hand coordination, and executive function, among subjects living in neighborhoods with a greater number psychosocial hazards (e.g., number of violent crimes, emergency calls, off-site liquor licenses as assessed by investigators) (Glass et al., 2009) (Table 5-10). Results were adjusted for age, sex, race/ethnicity, education, testing technician, and time of testing. Subjects living near more psychosocial hazards had slightly higher tibia Pb levels. In support of these results, several studies have found Pb-stress interactions in impaired learning and memory of adult animals with Pb exposures

beginning in gestation and lasting through post-weaning or to the time of testing (Section 5.3.2.3).

The 2006 Pb AQCD (U.S. EPA, 2006b) described cross-sectional associations of both blood and tibia Pb levels with poorer cognitive performance among 141 NAS men (Payton et al., 1998). Several recent, larger cross-sectional NAS analyses corroborated previous findings for bone Pb but generally indicated weak associations with concurrent blood Pb levels and only in groups with specific genetic variants. In contrast with the longitudinal analyses, Weisskopf et al. (2007b) found that repeat measures of bone Pb levels were inconsistently associated with cognitive function (improved and poorer performance) in cross-sectional analyses. Among 720 NAS men 45 years of age and older, higher concurrent blood and bone Pb levels were associated with lower MMSE scores among 149 ALAD-2 carriers (Weuve et al., 2006), with a larger decrease found for an increase in blood Pb level. A 3 μg/dL higher concurrent blood Pb level (the interquartile range) was associated with a 0.26 point lower mean MMSE score (95% CI: -0.54, -0.01) among ALAD-2 carriers and a 0.04 point lower score (95% CI: -0.16, -0.07) among noncarriers. A subsequent NAS analysis (n = 486-959) did not find a consistent direction of modification of the association of blood or bone Pb levels with tests of cognitive function in various domains by ALAD genotype (Rajan et al., 2008). An interaction between higher tibia Pb level and ALAD-2 genotype was found only for visuospatial skills (constructional praxis test), and between patella Pb level and ALAD-2 genotype for perceptual speed (pattern comparison test). The potential direction of effect modification by the ALAD-2 genotype is not clear as the greater affinity of the ALAD-2 enzyme subunit for Pb may increase risk of Pb-associated health effects by increasing blood Pb levels, or it may diminish Pb-associated health effects by sequestering Pb in the bloodstream and decreasing its bioavailability.

Cross-sectional studies examined a larger number of potential confounding factors than did longitudinal analyses. The NAS found blood and bone Pb-associated decrements in cognitive function with adjustment for dietary factors, physical activity, medication use, and comorbid conditions (Rajan et al., 2008; Weuve et al., 2006) (Table 5-10). As in the BMS and NAS, tibia and patella Pb levels were more consistently associated with cognitive performance than was blood Pb levels in 587 healthy women in the Boston, MA area participating in the Nurses' Health Study (Table 5-10) (Weuve et al., 2009). Additional potential confounding factors examined in this group included use of aspirin, ibuprofen, or vitamin E, mental health, and antidepressant use. Blood, patella, and tibia Pb levels were measured between ages 47 and 74 years and an average of 5 years before cognitive testing. Contrary to expectation, higher patella and tibia Pb levels were associated with higher scores on the “f” naming test (naming words that begin with f). In separate models, the “f” naming test was omitted from a composite index of all cognitive

tests performed by phone, and a one SD higher tibia Pb level was associated with 0.051-point lower (95% CI: -0.10, -0.003) composite cognitive function z-score (Table 5-10). A similar magnitude of decrease was estimated for an increase in age of 3 years in these women. The magnitude of association was smaller for an SD increase in patella Pb level (-0.033 [95% CI: -0.080, 0.014]), and a weak association was found for an SD unit increase in blood Pb level (-0.016 [95% CI: -0.071, 0.039]).

Several analyses of the large, U.S.-representative NHANES III (1991-1994) population of men and women investigated effect modification by age and genetic variants. Only blood Pb levels were available and were measured in samples collected concurrently with cognitive testing. These analyses adjusted for several of the same potential confounding factors as other studies, with the exception of smoking. Krieg and Butler (2009) found blood Pb level to be associated weakly with poorer performance on tests of learning and visuospatial skills among adults ages 20-39 years and inconsistently in adults ages 40-59 years. Krieg et al. (2009) further found inconsistent associations with word and story recall in adults ages ≥ 60 years. Because of the different types and numbers of tests administered, it is difficult to compare findings between adults less than and greater than age 60 years. In the subset of the population with genetic analysis, blood Pb-cognitive function associations were not found to be modified by ALAD genetic variants in a consistent direction (Krieg et al., 2009). Among adults ages 20-59 years and ≥ 60 years, higher concurrent blood Pb level was associated with a larger decrement in performance on some tests in ALAD-2 carriers and other tests in ALAD -1 subjects (Table 5-10). Krieg et al. (2010) found differences in the association between concurrent blood Pb level and scores on a symbol-digit substitution test by the VDR variants, rs731236 and VDR rs2239185, and by the VDR haplotype, which have unclear functional relevance. Similar to observations in adolescent NHANES participants (Section 5.3.2.5), results were not uniform across the various tests. However, for several tests, blood Pb level was associated with greater decrements in cognitive performance among adults with the CC genotypes of VDR variants.

Other cross-sectional studies with fewer subjects generally produced results consistent with those from the larger studies described above. A study of 188 rural Chinese men and women found a weak association between higher plasma Pb levels and a lower composite cognitive score based on a battery of in-person administered tests (Gao et al., 2008). Results were adjusted for age, sex, education, BMI, or APOE-ε4 in individual ANCOVA analyses. Smoking and alcohol use were not associated with cognitive performance in this group. Pb in plasma is not bound to erythrocytes, as is about 99% of blood Pb, and is the fraction delivered directly to soft tissue (Chuang et al., 2001; Hernandez-Avila et al., 1998). The results of Gao et al. (2008) may provide information on the cognitive effects of a more bioavailable fraction of Pb dose; however, because there is little investigation

of plasma Pb, firm conclusions are not warranted. Among 47 men and women in Rochester, NY (age 55-67 years), subjects in the highest two tertiles of calcaneal bone (heel bone with higher turnover rate than tibia) Pb level performed worse on delayed matching-to-sample and paired associated learning tasks than subjects in the lowest tertile (exact Pb levels in tertiles not reported) (van Wijngaarden et al., 2009). In analyses of tibia Pb levels, subjects in the highest tertile of tibia Pb level did not consistently perform worse on the various cognitive tests (Table 5-10).

Adults with Occupational Pb Exposures

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that in adults, blood Pb levels were associated with cognitive function more consistently among those with occupational Pb exposures. These findings were supported by results from a few recent studies of occupationally-exposed adults. Several of these associations were found with adjustment for fewer but a similar set of potential confounding factors as in nonoccupational studies; however, other occupational exposures were not considered. A prospective analysis was conducted in former male Pb battery workers whose occupational exposure had ceased 0.02 to 16 years (median: 6) before follow-up testing in 2001-2004 (Khalil et al., 2009a). Subjects included 83 of 288 workers (in 2004 mean age: 54 years, median tibia Pb level: 57 μg/g) and 51 of 181 controls (mean age: 55 years, median tibia Pb level: 12 μg/g) from the 1982 Lead Occupational Study in Pennsylvania. While the follow-up participation was low, participation was not biased to poor performers on cognitive tests at baseline. In former Pb-exposed workers, a 10 μg/g higher peak tibia Pb levels was associated with a -0.352 change in total cognitive function score (e.g., learning, memory, executive function, general intelligence, spatial function, psychomotor speed) between 1982 and 2004. In controls, higher tibia Pb levels were associated with improved performance on several tests. Results were adjusted for age, education, income, blood pressure, years of employment, years since last worked, smoking, alcoholic drinks/week, and baseline score. Cross-sectional associations indicated stronger associations of concurrent tibia Pb level than concurrent blood Pb level (median: 12 μg/dL) with poorer cognitive performance in former Pb-exposed workers. In controls, higher concurrent blood Pb levels were associated with larger decrements in cognitive performance. As in nonoccupationally-exposed adults, the stronger findings for tibia Pb levels in former Pb-exposed workers indicate stronger effects of long-term cumulative Pb exposures than recent exposures on cognitive function. The associations for concurrent blood Pb levels in controls also may reflect effects of past exposures.

Blood and tibia Pb levels also were associated with cognitive performance in a follow-up of 652 Pb-exposed workers (mean age: 43.4 years, mean blood Pb level: 30.9 μg/dL) in Korea, whose patella Pb levels were measured (Dorsey et al., 2006). Higher patella Pb levels were associated with poorer manual dexterity, executive function, and verbal memory with adjustment for age, sex, education, and job duration. The associations for patella Pb level were not as strong as those previously found for either blood or tibia Pb levels in these workers (Schwartz et al., 2005; Schwartz et al., 2001).

Other occupational studies aimed to characterize factors that either mediate or modify the association between Pb biomarkers and cognitive function. Both a working lifetime time-weighted integrated blood Pb level (an index of cumulative exposure) ($p = 0.09$) and tibia Pb level ($p = 0.08$) were associated with longer times to complete the grooved pegboard test among current Pb smelter workers (Bleecker et al., 2007b). In the same workers ($n = 112$, mean age: 38 years), higher time-weighted integrated blood Pb level was associated with decrements in executive function, learning, and memory among those with lower cognitive reserve (i.e., ≥ 12th grade reading level by Wide Range Achievement Test-R) (Bleecker et al., 2007a). Subjects with lower and higher cognitive reserve were matched by blood Pb level (mean: 26 μg/dL), and results were adjusted for age, depression scale, and current alcohol use.

Apolipoprotein E is a transport protein for cholesterol and lipoproteins and has been found to regulate synapse formation (connections between neurons). A genetic variant, called the ApoE-ε4 allele is a haplotype between 2 exonic SNPs and has been associated with a two-fold increased risk of developing Alzheimer's disease, although the majority of such individuals still do not develop the disease. Thus, it is biologically plausible that ApoE-ε4 carriers may be biologically susceptible to cognitive dysfunction. A study of 529 U.S. male, former tetra-ethyl Pb workers found that higher peak tibia Pb levels were associated with lower scores on tests of executive function, vocabulary, and memory (Stewart et al., 2002), and for several tests, larger decrements among the 118 men with at least one ApoE-ε4 allele. Results were adjusted for age, race, education, depression, testing technician, and visit number. The group with at least one ApoE-ε4 allele had slightly higher peak tibia Pb levels (mean: 26.2 versus 23.1 μg/g) and a larger percentage of non-white subjects but were similar in age, education, and time since employment.

Summary of Cognitive Function in Adults

In summary, consistent with evidence described in the 2006 Pb AQCD, recent studies found that higher bone Pb levels were associated decrements in cognitive function in adults without occupational Pb exposure (Table 5-10). Much of this evidence was provided by analyses of the BMS and NAS, with additional findings reported in the

Nurses' Health Study and smaller populations. Nonetheless, the multiple risk factors and health outcomes examined in most of these cohorts reduces the likelihood of selection bias by Pb exposure or cognitive function. While the NAS and Nurses' Health Study included primarily white men and white women, respectively, the BMS examined a more diverse population of men and women of several different race/ethnicities. There was variability in associations across the various domains of cognitive function tested within studies; however, higher bone Pb levels were associated with decrements in most of the tests performed. In several populations, higher bone Pb levels were associated with decrements in executive function, visuospatial skills, learning, and memory.

Key evidence for bone Pb-associated cognitive decrements was provided by recent prospective analyses that demonstrated that higher tibia (means 18.8, 20 µg/g) and patella (mean 25 µg/g) bone Pb levels measured at baseline were associated with subsequent declines in cognitive function over 2- to 4-year periods (Bandeen-Roche et al., 2009; Weisskopf et al., 2007b). These findings indicate that long-term Pb exposure may contribute to ongoing declines in cognitive function in adults. These associations were found with adjustment for potential confounding by age, education, smoking, and alcohol use in the NAS and age, sex, race, household wealth, and education in the BMS.

Supporting evidence was provided by most cross-sectional analyses that adjusted for several of the potential confounding factors described above plus dietary factors, physical activity, medication use, and comorbid conditions (Rajan et al., 2008; Weuve et al., 2006). Cross-sectional studies generally demonstrated larger decrements in cognitive function in adults in association with tibia or patella Pb levels than with concurrent blood Pb levels. In comparisons of associations with patella and tibia Pb levels in the NAS and Nurses' Health Study, tibia Pb levels were not consistently associated with larger decreases in cognitive performance (Weuve et al., 2009; Weisskopf et al., 2007b). In NHANES analyses, concurrent blood Pb levels were associated with lower cognitive function in particular age and genetic variant subgroups but not consistently across the various cognitive tests evaluated (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). NHANES did not have bone Pb measures for comparison.

Because bone Pb is a major contributor to blood Pb levels, blood Pb level also can reflect longer term exposures, including higher past exposures, especially in adults without occupational exposures. Thus, in the NHANES results, it is difficult to characterize the relative contributions of recent and past Pb exposures to the associations observed between concurrent blood Pb level and cognitive function. In other cohorts, the discrepant findings for blood and bone Pb levels indicate that cumulative Pb exposure that likely included higher past exposures, may be a better predictor of cognitive function in adults than is blood Pb level. Additional support for the effects of cumulative or past

Pb exposure is provided by analyses of a few child cohort as adults, which indicated that childhood tooth (from ages 5-8 years) and blood Pb levels (e.g., age 10 years) were associated with decrements in cognitive function in adults ages 19-30 years) (Mazumdar et al., 2011; Bellinger et al., 1994a). An uncertainty related to the evidence for cognitive function decrements associated with bone Pb levels is the potential residual confounding by age. Although studies adjusted for age, the high correlation between increasing age and bone Pb levels (Section 4.3.5) makes it difficult to distinguish the independent effect of Pb exposure. However, the coherence with evidence for cognitive function decrements associated with long-term Pb exposure in animals provides support for associations observed in human adults.

Cross-sectional analyses provided information on potential effect modification of bone Pb- and blood Pb-associated decrements in cognitive function in adults by race, psychosocial stress, and genetic variants. Inconsistencies were found for effect modification by race in the BMS, ALAD-2 genotype in the NAS and NHANES, and VDR genotype in NHANES. Larger tibia Pb-associated decrements in cognitive function was found in NAS men with HFE variants and in BMS subjects living near more psychosocial hazards. Evidence does not clearly indicate whether the observed effect modification reflects chance, a change in the toxicokinetics of Pb that alters Pb dose at the biological site of action, or a direct biological interaction that increases the toxicity of Pb in the target tissue. However, such effect modification serves to strengthen inferences about associations between Pb biomarkers and cognitive function since it is unlikely that potential confounding factors vary by levels of the modifying factor, particularly genetic variants. However, because there is little available evidence and inconsistent evidence for some factors, firm conclusions regarding effect modification are not warranted.

In contrast with nonoccupationally-exposed adults, in adults with former and current occupational Pb exposures, cognitive function decrements were associated with both blood (means: 12 [former workers]-31 μg/dL) and bone Pb levels. Thus, among Pb-exposed workers, both current and cumulative Pb exposures may affect cognitive function. Several of these studies considered confounding by a similar set of potential confounding factors as studies of adults without occupational Pb exposures but did not consider other occupational exposures. In the prospective study of former Pb workers, peak tibia Pb levels were associated more strongly with cognitive performance than were blood Pb levels (Khalil et al., 2009a). Thus, in the absence of higher current Pb exposures, cumulative Pb exposures may have a greater effect on cognitive function in adults.

5.3.3 Attention-related Behavioral Problems in Children

The effects of Pb exposure on attention-related behavioral problems such as inattention, impulsivity, hyperactivity, and ADHD have not been examined as extensively as effects on cognition. Behavioral effects are more complex to study than are cognitive effects, particularly FSIQ. There are fewer objective tests of attention-related behavioral problems with as strong psychometric properties or as rigorous validation as IQ tests. In several studies, attention-related behavioral problems were assessed using teacher and/or parent ratings which are subject to greater measurement error. However, domain-specific neuropsychological assessments are advantageous as they may provide greater insight into whether there is a particular domain more susceptible to the effects of Pb exposure. As with cognitive function, in the evaluation of epidemiologic evidence for attention-related behavioral problems, greater emphasis was placed on evidence from neuropsychological tests than from parent or teacher ratings and prospective studies with repeated assessments of blood Pb levels and behavior, studies of older children in whom outcomes are more reliably measured, and studies of children whose blood Pb levels are less influenced by higher past Pb exposures. Similar to cognitive function, associations between blood Pb levels and attention-related behavioral problems potentially may be confounded by factors such as parental SES, education, and IQ, quality and stability of the caregiving environment, and nutritional status. Accordingly, greater weight was given to studies with greater consideration for potential confounding in the study design or in statistical analyses. Consideration also was given to studies assessing effects relevant to blood Pb levels in contemporary U.S. children (i.e., <5 µg/dL).

Some studies that found associations between concurrent blood Pb levels and attention-related behavioral problems were not major considerations in drawing conclusions and are not discussed in detail in the following sections. These studies examined populations that have high prevalence of prenatal alcohol or drug exposure (Chiodo et al., 2007; 2004), or had earlier childhood chelation (Chen et al., 2007), and thus may not be representative of current children in the U.S. population. Others had limited consideration for potential confounding (Liu et al., 2011b), or examined infants in whom inattention ratings may not predict behavior in later childhood (Plusquellec et al., 2007).

5.3.3.1 Inattention and Impulsivity

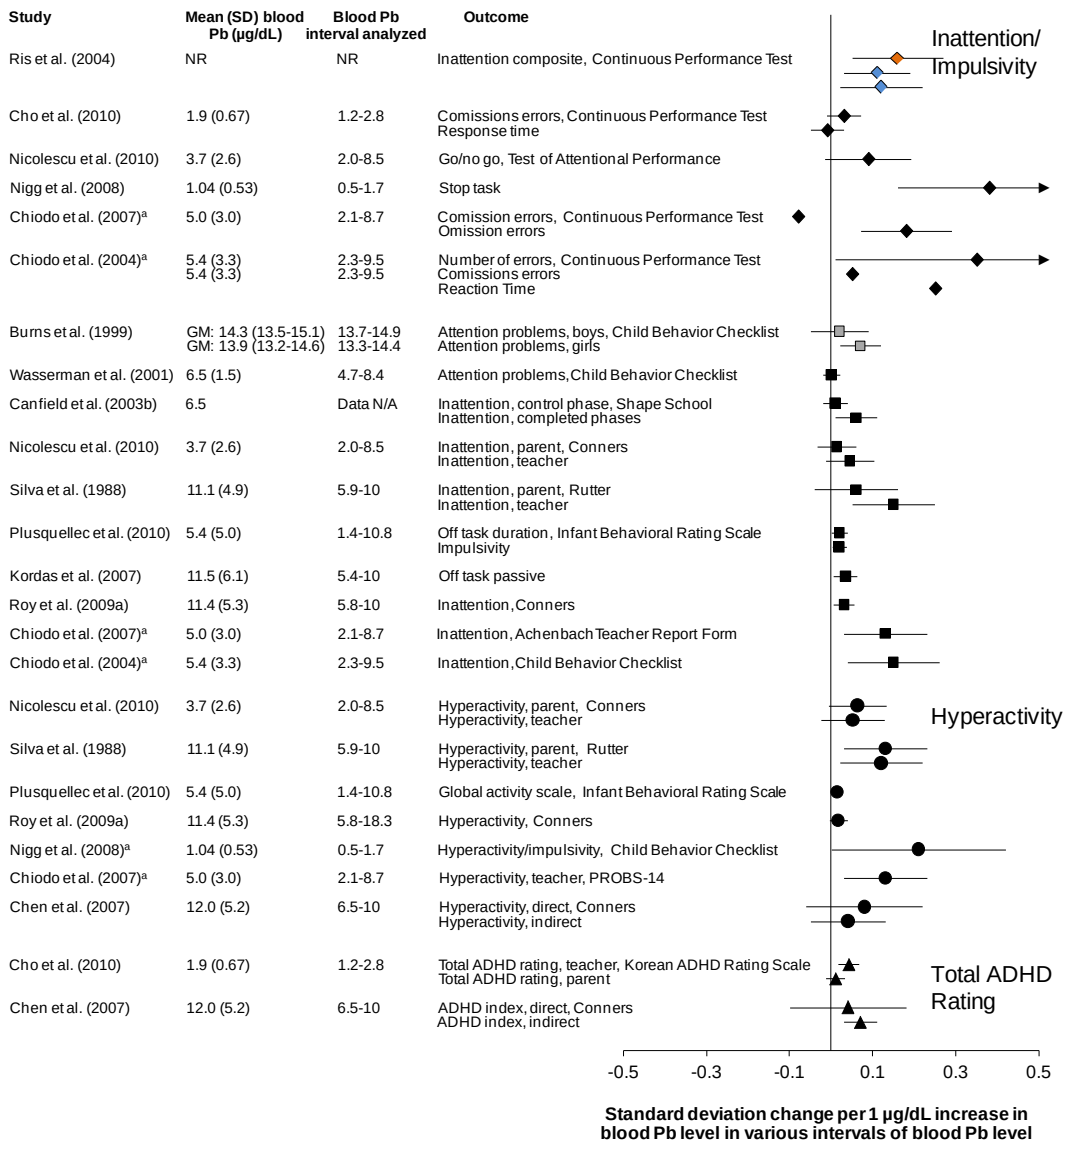
Epidemiologic studies of Inattention and Impulsivity in Children

Attention is the ability to maintain a consistent focus on an activity or relevant stimuli and can be assessed by examining sustained attention, impulsivity, or distractibility. Several epidemiologic studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) reported associations between blood, tooth, or bone Pb levels with inattention in children ages 8-17 years, including prospective studies described in previous sections for cognitive function (Ris et al., 2004; Fergusson et al., 1993; Leviton et al., 1993). As described in this section, recent studies also found associations of blood Pb levels with inattention in children ages 8-17 years. Many previous studies of inattention included children with higher blood Pb levels than those of most current U.S. children. Recent studies, most of which were cross-sectional, provided evidence of blood Pb-associated inattention in populations of children with mean concurrent blood Pb levels 2 to 5 µg/dL (Cho et al., 2010; Nicolescu et al., 2010; Plusquellec et al., 2010); however, limitations include the cross-sectional design of studies and potential influence of higher past Pb exposures. In the collective body of literature, most evidence was for inattention rated by teachers, parents, or blinded examiners; however, associations were consistently found for more objective measures such as the continuous performance test (CPT) (Figure 5-10 and Table 5-11). Thus, evidence does not indicate undue influence by biased reporting of inattention by parents of children with high Pb exposures. Epidemiologic findings for inattention and impulsivity are supported by the coherence of findings in Pb-exposed animals of poorer response inhibition in Schedule Controlled Behavior Tests and poorer performance on signal detection tests with distracting stimuli (discussed below). In particular, both evidence in children and animals indicates Pb-associated poorer performance on test of response inhibition, i.e., continued responses to stop signals.

Most studies that assessed inattention with the objective CPT found associations with blood Pb level (Figure 5-10 and Table 5-11), including prospective studies in Cincinnati and in Chelsea/Sommerville, MA, which indicated associations of higher prenatal or earlier childhood blood Pb levels or tooth Pb levels with increases in commission and omission errors or reaction time in adolescents and young adults (Ris et al., 2004; Bellinger et al., 1994a). In the CPT, subjects are assessed for their ability to maintain focus during a repetitive task and respond to targets or inhibit responses. These findings from prospective studies characterized the temporal sequence between Pb exposure and inattention better than cross-sectional studies and made reverse causation a less likely explanation for observed associations. These studies recruited cohorts from schools or prenatal clinics and had moderate to high follow-up participation that was not conditional on blood or tooth Pb levels, which reduces the likelihood of selection bias. Among

primarily white, higher SES young adults ages 19-20 years, Bellinger et al. (1994a) found that compared with the group with age 5-8 year tooth Pb levels 2.9-5.9 ppm, the group with tooth Pb levels >19.9 ppm had fewer correct response on the CPT and had longer reaction times for correct responses but did not commit more commission errors (responding to a nontarget). In the mostly African-American, lower SES Cincinnati cohort, Ris et al. (2004) found increased inattention (composite of CPT outcomes) in association with prenatal maternal, age 3-60 month average, and age 78 month blood Pb levels in adolescents ages 15-17 years, particularly among males. Although blood Pb levels at older ages were not examined and results do not exclude an effect of more recent Pb exposures, the combined evidence from these prospective studies points to an effect on inattention of cumulative earlier childhood Pb exposures. Both studies considered several potential confounding factors, including SES, parental IQ, maternal education, and self drug use. HOME score was considered only in the Cincinnati cohort. Ris et al. (2004) also considered potential confounding by prenatal drug and alcohol exposure, birth outcomes, and iron status.

Recent studies that assessed inattention with neuropsychological tests, primarily in non-U.S. populations, found Pb-associated increases in inattention, although all were cross-sectional design and did not consider potential confounding by parental caregiving quality. Further, sufficient data were not provided to assess whether participation was biased to those with higher Pb exposure and inattention. A study in children ages 8-11 years in Korea demonstrated poorer performance on some indices of the CPT with relatively low blood Pb levels (mean 1.9 µg/dL) (Cho et al., 2010); however, the contribution of higher earlier Pb exposures cannot be excluded. Specifically, higher concurrent blood Pb levels were associated with more commission errors, but weakly with other parameters of the CPT (Figure 5-10 and Table 5-11). Results were adjusted for age, sex, paternal education, maternal IQ, child IQ, city of residence, birth weight, and urinary cotinine, the latter of which was more strongly associated with CPT performance than blood Pb level and the primary cause of attenuation of blood Pb effect estimates. Cho et al. (2010) found that mean blood Pb levels were similar in children with and without (1.80 and 1.93 µg/dL, respectively, $p = 0.32$) parental report of history of neuropsychiatric disease (e.g., ADHD, learning disability, depression, obsessive-compulsive disorder); however, history may not accurately represent current parental caregiving quality.



[a]Standard errors were estimated from p-values or sufficient data were not provided to calculate 95% CIs.

Note: Regression coefficients were scaled to their standard deviation to facilitate comparisons among tests with different scales. Small effect estimates should not necessarily indicate lack of effect or weak effect. Results are categorized by outcome category: inattention/impulsivity (with objective tests presented first), hyperactivity ratings, total ADHD ratings. Within categories, results generally are presented in order of strength of study design. Effect estimates are standardized to a 1 µg/dL increase in blood Pb level in the interval from the 10th percentile to the 90th percentile or 10 µg/dL, whichever was lower. For studies with 10th percentiles of blood Pb level > 10 µg/dL, effect estimates are standardized to a 1 µg/dL increase in blood Pb level in the interval from the 10th to 90th percentile of blood Pb level. The percentiles are estimated using various methods and are approximate values. Effect estimates are assumed to be linear within the 10th to 90th percentile interval of blood Pb level. Gray, orange, blue, and black symbols represent associations with lifetime average, prenatal (maternal), earlier childhood, and concurrent blood Pb levels, respectively.

[d]Results represent the change in false alarm rate.

[e]Sufficient data were not provided to calculate 95% CIs.

[f]Results not presented in Figure 5-10 because OR or RR reported in papers.

Response inhibition is a measure of impulsivity and in children has been assessed with stop signal tasks, which measures the execution of action and the inhibition of that action when given a stop signal. Recent cross-sectional studies found that children with higher concurrent blood Pb levels had increased responses with stop signals. Among children ages 8-12 years in Romania, a 1 µg/dL increase in concurrent blood Pb level was associated with a 8.9% (95% CI: -1.3, 19.3) increased false-alarm rate in responses to stop signals with adjustment for city, sex, age, computer experience, handedness, eye problems, number of siblings, parental education, prenatal alcohol and smoking exposure, and parental report of parental psychopathology (Nicolescu et al., 2010). It is uncertain how history of parental psychopathology may be related to current caregiving quality. Children in one town lived near a metal processing plant; however, blood Pb levels of Al and Hg (other neurotoxic metals), were not associated with the stop signal task. In a case-control study of children with ADHD, Nigg et al. (2008) found that higher concurrent blood Pb level was associated poorer response inhibition on a stop task, which in turn was associated with higher hyperactivity/impulsivity ratings. Path analysis showed that the association between blood Pb level and hyperactivity/impulsivity ratings was mediated by poorer performance on the stop task.

In addition to objective tests of attention, studies found Pb-associated increases in inattention as rated by teachers, parents, and independent examiners (Figure 5-10 and Table 5-11). Results from prospective studies indicated associations in children ages 7-13 years in Australia, New Zealand, and Boston, MA (Burns et al., 1999; Fergusson et al., 1993; Leviton et al., 1993) but less so in younger children ages 4-5 years in Rochester

and Yugoslavia (Canfield et al., 2003b; Wasserman et al., 2001). These studies had population-based recruitment and moderate to high follow-up, without indication of biased participation by children with higher blood Pb levels and attention problems. Among older children, inattention was associated with higher lifetime (to age 11-13 years) average (Burns et al., 1999), and tooth (collected at ages 6-8 years) Pb levels (Fergusson et al., 1993; Leviton et al., 1993). In separate cohorts, lifetime average blood Pb level (Burns et al., 1999) and tooth Pb level (Leviton et al., 1993) were associated with higher inattention ratings among girls than boys. With the exception of the Boston, MA analysis, consideration of potential confounding did not differ widely among the prospective studies, with most adjusting for maternal education, SES, and parental caregiving quality (e.g. HOME) (Table 5-11). Prospective studies that found associations examined higher blood Pb levels. The mean lifetime (to age 11-13 years) average blood Pb level in the Port Pirie, Australia cohort was ~14 µg/dL (Burns et al., 1999). Chandramouli et al. (2009) did not find an association between higher age 30 month blood Pb levels and higher ratings of inattention in U.K. children ages 7-8 years. Associations with inattention were not found in the Rochester and Yugoslavia cohorts with lower concurrent blood Pb levels, means 6-7 µg/dL (Canfield et al., 2003b; Wasserman et al., 2001). The studies in the Rochester and Yugoslavia cohorts examined lower blood Pb levels but also had smaller sample sizes and examined younger children ages 4-5 years, in whom patterns of behavior are less well established and in whom inattention ratings may be less reliably measured. Nonetheless, these few weak findings do not mitigate the otherwise compelling evidence, including that for attention-related behavioral problems assessed with neuropsychological tests and that observed in animals. Canfield et al. (2003b) found associations between higher concurrent blood Pb level and higher ratings of inattention, but they were attenuated with adjustment for child color and shape knowledge and FSIQ, which suggested that poorer knowledge of the task parameters may increase distraction. However, other studies found associations between blood Pb level and inattention with adjustment for child IQ (Cho et al., 2010; Nigg et al., 2008), indicating the relationship between inattention and cognitive function may vary across populations.

Several cross-sectional studies found associations between higher concurrent blood Pb level and inattention among children, with several studies examining older children, 8-17 years (Nicolescu et al., 2010; Nigg et al., 2008; Silva et al., 1988). These studies had population-based recruitment but did not provide sufficient information to assess potential selection bias. While most of these studies examined potential confounding by parental education or cognition, and parental history of psychopathology, none considered parental caregiving quality. Whereas a previous study in New Zealand examined children with relatively high blood Pb levels (mean 11 µg/dL) (Silva et al., 1988), some recent studies provided evidence of association between blood Pb level and

higher ratings of inattention in populations with relatively low concurrent blood Pb levels (means: 1, 3.7 µg/dL) (Nicolescu et al., 2010; Nigg et al., 2008). However, contributions from higher past Pb exposures cannot be excluded. Past Pb exposures especially may have an influence in the study of children ages 8-12 years in Romania, 55% (n = 46/83) of whom lived near a former metal processing plant and had higher concurrent blood Pb levels (mean 5.1 versus 3.2 µg/dL) (Nicolescu et al., 2010). Among all subjects, a 1 µg/dL increase in concurrent blood Pb level was associated with a 4.5% higher (95% CI: -1.3, 10.3%) teacher rating of inattention and a weaker, imprecise 1.3% (95% CI: -3.3, 5.9) higher parent rating. Blood Pb levels were not correlated with blood levels of Al or Hg, and neither of these other metals were associated with inattention ratings. The association did not change substantially in an analysis that excluded the 5 children with blood Pb levels ≥ 10 µg/dL. Adjustment for city, sex, age, computer experience, handedness, eye problems, number of siblings, parental education, prenatal smoking exposure, prenatal alcohol exposure, and parental history of psychological or psychiatric problems resulted in less precise blood Pb level effect estimates, although investigators did not report the magnitude of change in the effect estimate.

Consistent with Nicolescu et al. (2010), Nigg et al. (2008) found associations of concurrent blood Pb levels with parent and teacher ratings of a composite hyperactivity/impulsivity index in a group of children (location not reported) with and without ADHD (ages 8-17 years) with a mean blood Pb level of ~1 µg/dL. The case-control design of the study could have resulted in biased participation of ADHD children with higher blood Pb levels. Nigg et al. (2008) also found the Pb-associated increase in hyperactivity/impulsivity to be independent of the association with IQ using regression-based path analysis, a more rigorous method to characterize the impact of one variable on the association of another in the model after controlling for other previous variables. With adjustment for sex and income, concurrent blood Pb level was directly associated with hyperactivity/impulsivity, and the association was not completely mediated by the blood Pb-IQ association. Instead, the association between blood Pb level and IQ was found to be mediated by the association with hyperactivity/impulsivity. Other potential confounders including parental IQ and caregiving quality were not examined. Other recent cross-sectional studies of older children found associations between higher concurrent blood or hair Pb level and higher ratings of inattention (independent examiner or parent) in children in Mexico and China living near Pb sources (Bao et al., 2009; Kordas et al., 2007). As in most other cross-sectional studies, these results were adjusted for SES and parental education.

Cross-sectional studies that included younger children (ages 3-5 years) also found associations between concurrent blood Pb level and higher inattention as rated by teachers or study examiners (Plusquellec et al., 2010; Roy et al., 2009a). In these younger

children, attention-related behaviors may be less reliably measured and may not predict later childhood behavior. A study conducted in Inuit children, ages 5-6 years, living in Quebec, Canada reported associations between blood Pb levels and measures of inattention with consideration of several potential confounding factors (Plusquellec et al., 2010). Concurrent blood Pb level but not cord blood Pb level was associated with impulsivity and duration of off task behavior as rated by study examiners (Plusquellec et al., 2010). Fraser et al. (2006) additionally indicated that at ages 5-6 years, the relationship between concurrent blood Pb level and motor function (i.e., transversal sway, reaction time) may be mediated by the association between blood Pb level and inattention/impulsivity. The various associations were adjusted for different factors but included SES, caregiver education, birth weight, and blood hemoglobin. HOME score and micronutrient levels were not associated with inattention or impulsivity and thus were not included in models. In this population that has high consumption of fish, blood levels of polychlorinated biphenyls and Hg were not associated with inattention or impulsivity ratings. Other recent cross-sectional studies that included younger children (ages 3-7 years) found associations between higher concurrent blood Pb level and higher parent or teacher ratings of inattention in populations with higher blood Pb levels (mean 11.4 µg/dL or median 13.2 µg/dL) (Liu et al., 2011b; Roy et al., 2009a). While these studies adjusted for or considered potential confounding by SES, child age, and parental education, they did not examine potential confounding by parental caregiving quality.

Toxicological Studies of Inattention and Impulsivity

The associations described in the preceding section between blood Pb level and inattention and impulsivity in children are supported by findings in animals for Pb-induced impaired ability to inhibit inappropriate responses and increased perseveration. In animals, tests of response inhibition include Signal Detection with Distraction, Differential Reinforcement of Low Rates of Responding (DRL), Fixed Interval (FI) testing, FI with Extinction, or Fixed Ratio (FR)/waiting-for-reward, with impulsivity indicated by premature responses, decreased pause time between two scheduled events, and increased perseveration. Some of these tests also have been used to assess learning (Section 5.3.2.3), and the interactions observed between Pb exposure and maternal or offspring stress also may apply to effects on impulsivity. Multiple earlier studies and those included in the 2006 Pb AQCD showed that early life Pb exposure impaired response inhibition as assessed with these aforementioned tests, and recent studies provide supporting evidence. Discrimination reversal, which also measures response inhibition by rewarding the withholding of responses, has been shown to be affected by Pb exposure. Spatial and non-spatial discrimination reversal (i.e., reversal of a previously learned habit) was significantly affected after developmental Pb exposure and

was exacerbated with distracting stimuli. The collective evidence indicates that impulsivity in rodents and nonhuman primates is significantly affected by Pb exposure that results in blood Pb levels in the range relevant to humans, i.e., 11-31 µg/dL.

Toxicological studies provide more consistent evidence for the effects of Pb exposure on impulsivity in animals than on sustained attention. The 2006 Pb AQCD (U.S. EPA, 2006b) reported inconsistent findings for the effects of Pb exposure on sustained attention deficits in animals as assessed by a signal detection test with distracting stimuli, a test recording omissions after exposure to an external distraction. In this test, animals earn food rewards by discriminating correctly between a target and distracter light. Postweaning Pb exposure that produced blood Pb levels of <5, 16, or 28 µg/dL did not affect performance in the signal detection test with distracting stimuli in adult rats (Brockel and Cory-Slechta, 1999a). A similar lack of effect was reported in a recent study of female rats exposed to 20 or 300 ppm Pb acetate in drinking water during lactation (PND1-PND30) with resultant blood Pb levels on PND52 of 13 or 31 µg/dL, respectively (Stangle et al., 2007). However, in this study, Pb exposure induced impulsivity as indicated by premature responses in a discrimination reversal task. Impulsivity was not improved with the chelator succimer, indicating persistence of effects. Impulsivity was found in monkeys exposed to Pb from birth to time of testing at age 3-4 years with blood Pb levels 15 and 25 µg/dL; however, effects were reversible, as Pb-exposed monkeys did not improve performance as quickly but eventually acquired reinforcement rates equal to that in controls (Rice and Gilbert, 1985). Previous evidence indicated that Pb exposure of laboratory animals induces distractibility. Spatial and non-spatial discrimination reversal was significantly affected after lifetime Pb exposure in monkeys ages 9-10 years (blood Pb levels 15, 25 µg/dL) and was exacerbated with distracting stimuli. Repeated learning testing revealed that these deficits likely were not due to sensory or motor impairment (Gilbert and Rice, 1987).

The effects of Pb exposure on inattention and impulsivity in the 1986 Pb AQCD were indicated by aberrant performance on operant conditioning tasks in rodents and non-human primates (U.S. EPA, 1986b). The 2006 Pb AQCD reported consistent findings for Pb exposure (producing blood Pb levels: 58-94 µg/dL) affecting FI response rates, by means of decreased interresponse times. Some studies indicated decreased interresponse times in animals with blood Pb levels 11-15 µg/dL (U.S. EPA, 2006b). The effects of Pb exposure on impulsivity also have been demonstrated as shorter time Pb-exposed animals will wait for reward in FR/waiting for reward testing. In this test, animals can obtain food by pressing a lever for a set number of times. Free food is delivered with increasingly long time intervals so long as animals inhibit additional lever presses. Animals can reset the schedule to return to the FR component at any time. Brockel and Cory-Slechta (1998) exposed male Long-Evans rats to 0, 50, or 150 ppm

Pb acetate in drinking water from weaning, which produced respective blood Pb levels of <5, 11, and 29 µg/dL after 3 months of exposure. After 40 days of exposure, the 150 ppm Pb-exposed rats responded more quickly in the FR component and reset the schedule (thus shortening the waiting period) more frequently than did the 50 ppm Pb-exposed rats and controls. In the waiting component, wait time was significantly lower in both Pb exposure groups compared to controls. The behavior of the 150 ppm Pb-exposed rats suggested a low tolerance for waiting, but 150 ppm Pb exposure also yielded more reinforcers per session and a higher response-to reinforcement-ratio than achieved by the 50 ppm Pb group and controls. Mechanistic understanding of the aforementioned Pb-induced impulsivity was provided by a study with similar postweaning dosing of 0, 50, and 150 ppm Pb that yielded respective blood Pb levels of <5, 10, and 26 µg/dL after 3 and 7 months of exposure. Administration of a D2 receptor agonist reversed the Pb-induced parameters assessed by FR schedule testing, suggesting a role for dopamine-like receptors in Pb-induced impulsivity (Brockel and Cory-Slechta, 1999b).

Pb-induced impulsivity appears to be related to emotionality, which was found in Pb-exposed rats trained to perform an olfactory discrimination task, albeit at higher Pb exposures than those relevant to humans. In this study, rats were given early postnatal Pb exposure (300 ppm Pb acetate via dam drinking water PND1-PND17 then either 20 or 300 ppm PND18-PND30 in their own drinking water) which produced blood Pb levels of 40-60 and 100-140 µg/dL). The offspring were tested as young adults on a food-motivated olfactory discrimination task in which rewards for correct responses were occasionally and unpredictably omitted. Pb-exposed animals were more sensitive both to their own errors and to reward omission than controls, suggesting a lowered capacity for regulating arousal and emotion. Administration of succimer, a chelating agent, after the Pb exposure period (PND31-PND52) normalized reactivity to reward omission and errors in the Pb-treated rats, but increased the reactivity in the control animals (Beaudin et al., 2007). Similar observations were made by the same laboratory for heightened reactivity to errors in tests of visual discrimination and visual sustained attention in rats exposed to 20 or 300 ppm Pb acetate in drinking water PND1-PND30 (Stangle et al., 2007)

In animals, Pb-induced increases in inattention have been indicated using tests that are not direct assessments of inattention but that examine behaviors linked to inattention. For example, a study reported that impaired performance on auditory threshold tasks in Pb-exposed monkeys was likely due to inattention (Laughlin et al., 2009). Rhesus monkeys were exposed to Pb acetate from gestation (drinking water of mothers, 3 months prior to mating) to birth or postnatally from birth to age 5.5 months at weaning and had resultant bone Pb levels at 11 years of 7 and 13 µg/g for prenatal and postnatal groups, respectively, and blood Pb levels during Pb exposure of 35 and 46 µg/dL, respectively. Animals were tested at age 13 years when blood Pb levels had returned to baseline levels.

The inability of some of the monkeys to engage or focus attention on the task at hand yielded fewer available measurements in Pb-exposed animals versus control rhesus monkeys. These observations were made in monkeys with higher peak blood Pb levels than those relevant to humans.

In summary, several studies in animals indicate that early developmental Pb exposure of rodents and non-human primates, some producing blood Pb levels relevant to humans, increases impulsivity as indicated by impaired response inhibition. Evidence for Pb-induced decrements in sustained attention is less consistent. The observations for Pb-induced increases in impulsivity in animals provide support for associations observed in children between blood and tooth Pb levels and impaired response inhibition and also higher ratings of inattention and impulsivity.

5.3.3.2 Hyperactivity

Studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) indicated associations between higher concurrent blood Pb level or tooth Pb level and higher parent and teacher ratings of hyperactivity in children ages 6-11 years in the U.S. and Asia (Rabinowitz et al., 1992; Silva et al., 1988; Gittleman and Eskenazi, 1983; Needleman et al., 1979; David et al., 1976). The case-control or cross-sectional design of studies limited understanding of the temporal sequence between Pb exposure and hyperactivity. Several recent studies, including a prospective study (Chandramouli et al., 2009), also found associations between blood Pb level and hyperactivity as rated by teachers and parents (Figure 5-10 and Table 5-11). Overall studies indicated associations with mean or group blood Pb levels >10 µg/dL.

The recent prospective study of children in the U.K. addressed some of the limitations of previous cross-sectional studies by demonstrating an association between higher earlier childhood (age 30 months) blood Pb level and higher teacher ratings of hyperactivity later in childhood at age 7-8 years with adjustment for several potential confounding factors, including home facilities score and family adversity index (Chandramouli et al., 2009). In addition to the prospective design, the study had a high participation rate at baseline and follow-up from a population with similar characteristics as reported in the U.K. census. Increases in hyperactivity were found primarily in the group of children with blood Pb levels >10 µg/dL and were independent of associations with IQ.

Among cross-sectional studies, adjustment for SES, maternal education and IQ was common; however, few adjusted for parental caregiving quality. Silva et al. (1988) and Nicolescu et al. (2010) respectively, adjusted for current and history of maternal psychopathology, whose relationships with parental caregiving quality are not well

characterized. Both studies found associations of concurrent blood Pb level with hyperactivity as rated by teachers and parents, and Silva et al. (1988) found the association in children age 11 years in New Zealand to persist with adjustment for child IQ. The group of children in New Zealand (Silva et al., 1988) had a higher mean concurrent blood Pb level than the group in Romania (Nicolescu et al., 2010) (11.1 versus 3.7 µg/dL). Other cross-sectional studies found associations with hyperactivity in younger children, in whom behavior may be rated less reliably. Plusquellec et al. (2010) found an association in children ages 5-6 years with relatively low concurrent blood Pb levels, mean 5.4 µg/dL, and found that HOME score and caretaker distress were not associated with hyperactivity. Roy et al. (2009a) found a Pb-associated increase in hyperactivity in children ages 3-7 years in India with a mean concurrent blood Pb level of 11.4 µg/dL.

Pb also has been associated with hyperactivity in animals, but the relevance to observations in children is not clear. In a recent study, Pb exposure from gestation to the early postnatal period (PND10) (low and high dose Pb: 10 and 42 µg/dL blood Pb level at PND10, respectively) increased activity of male mice at age 1 year with co-treatment with amphetamines but not female mice (Leasure et al., 2008). Without amphetamines, Pb induced less activity of mice, and the low Pb dose inhibited activity more than the high Pb dose did. In addition to the effects of Pb on impulsivity, Stangle et al. (2007) found Pb-induced decreases in arousal. In one theory of ADHD, low arousal levels contribute to excessive self-stimulation or hyperactivity such that an optimal level of arousal can be attained (Swanson et al., 2011).

5.3.3.3 Ratings of Attention Deficit Hyperactivity Disorder-related Behaviors

The 2006 Pb AQCD (U.S. EPA, 2006b) did not examine ADHD specifically. However, in addition to finding associations with inattention, impulsivity, and hyperactivity, some of the recent epidemiologic studies described in the preceding sections found associations between higher concurrent blood Pb level and higher parental and teacher ratings of ADHD-related behaviors (Cho et al., 2010; Nicolescu et al., 2010; Roy et al., 2009a), which are a composite of the various behaviors that are evaluated in the diagnosis of ADHD. The strengths and limitations of these studies have been described in the preceding sections. Main limitations were the cross-sectional design, lack of consideration for potential confounding by parental caregiving quality, and lack of validation of ADHD ratings with a clinical diagnosis. Thus, the evidence specifically for these total ADHD index ratings were emphasized less than evidence for inattention and impulsivity in drawing conclusions about the effects of Pb exposure on attention-related behavioral problems.

The large, U.S. representative analysis of children participating in NHANES 2001-2004 found an association between concurrent blood Pb level in children ages 8-15 years and parental assessment of child ADHD-related behaviors using the Diagnostic Interview Schedule for Children which uses DSM-IV criteria to identify children at increased risk of meeting diagnostic criteria for ADHD (Froehlich et al., 2009). Compared with children with concurrent blood Pb levels <0.8 µg/dL, children with concurrent blood Pb levels >1.3 µg/dL had elevated odds of parentally-rated ADHD-related behaviors with an OR of 2.3 (95% CI: 1.5, 3.8). These results were adjusted for current household smoking exposure, sex, age, race/ethnicity, income, preschool attendance, maternal age, and birth weight. A similar OR was estimated when children with concurrent blood Pb levels >5.0 µg/dL were excluded from the highest tertile. The strongest association was observed in children with both high blood Pb level and prenatal tobacco smoke exposure. Compared to children with blood Pb levels <0.8 µg/dL with no exposure to prenatal tobacco smoke, children with blood Pb levels >1.3 µg/dL and exposure to prenatal tobacco smoking had the highest odds of parentally-rated ADHD-related behavior (OR: 8.1 [95% CI: 3.5, 18.7]). Although ADHD-related behavior was associated with low concurrent blood Pb levels (1.3-5 µg/dL), the contribution of higher past Pb exposures of adolescents born in the late 1980s cannot be excluded. Roy et al. (2009a) also found an association with teacher ratings of ADHD-related behaviors using DSM criteria in children in Chennai, India; however, the study population included some very young children (i.e., age 3 years) and had relatively high blood Pb levels (mean: 11.4 µg/dL).

Other recent cross-sectional studies found Pb-associated higher ratings of ADHD-related behaviors using instruments that do not follow DSM criteria. Among children ages 8-11 years in Korea, Cho et al. (2010) found a stronger relationship with a total ADHD-related behaviors index as rated by teachers than parents. Mean ADHD ratings by teacher and parents were similar (both 9.1); however, parental ratings had greater variability (SD: 11.5 for parents and 8.6 for teachers), which may have contributed to differences in association. Among children in Romania, concurrent blood Pb level was associated similarly with parent and teacher ratings of ADHD-related behaviors (Nicolescu et al., 2010). As with individual attention-related behaviors described in preceding sections, blood Al and Hg levels were not associated with ratings of ADHD-related behaviors. Based on a log-linear model, a 1 µg/dL increase in concurrent blood Pb level within the 10th-90th percentile interval (1.8-7.1 µg/dL) was associated with a 4% increase (95% CI: 0, 10) in rating of ADHD-related behavior. The association did not change substantially in an analysis that excluded the 5 children with blood Pb levels ≥ 10 µg/dL. Both studies considered potential confounding by parental history of psychopathology. In Cho et al. (2010), children of parents with history of psychiatric disease had lower blood Pb levels. In Nicolescu et al. (2010), parental history of psychological or psychiatric problems was weakly correlated with parental ($r = 0.24$, $p \leq 0.05$) and teacher ($p = 0.12$) rating of

ADHD-related behavior, and ORs were fairly similar for ADHD score rated by teachers and parents. Although parental history of psychopathology was examined in a few studies, its relationship with current parental caregiving quality is not well characterized.

5.3.3.4 Attention Deficit Hyperactivity Disorder in Children

The 2006 Pb AQCD (U.S. EPA, 2006b) did not review studies of prevalence or incidence of ADHD diagnosis but noted lack of conclusive evidence for the effect of Pb exposure on ADHD based on a few small studies comparing blood Pb levels between children with and without hyperactivity as identified by parents, teachers, or schools (Gittleman and Eskenazi, 1983; David et al., 1972). As described in the previous section, several recent cross-sectional studies found associations of concurrent blood Pb level with parent and teacher ratings of a total ADHD index, a composite index of inattention, impulsivity, and hyperactivity. Results from a small body of recent studies also indicate associations of higher concurrent blood Pb level with prevalence of diagnosed ADHD in children ages 4-17 years (Nigg et al., 2010; 2008; Wang et al., 2008d; Braun et al., 2006). All of the studies were cross-sectional; thus, the temporal sequence between Pb exposure and ADHD incidence cannot be established. While there is coherence with evidence from prospective studies in other populations for associations of blood Pb levels with inattention, hyperactivity, and impulsivity, evidence specifically for ADHD prevalence was emphasized less than evidence for inattention and impulsivity in drawing conclusions about the effects of Pb exposure on attention-related behavioral problems.

Associations between concurrent blood Pb level and ADHD prevalence were found in case-control studies conducted in different populations of children. While a potential limitation of these studies is selection bias arising from the nonrandom population sample, a common strength is their independent diagnosis of ADHD in a structured manner using parental and teacher ratings of behavior followed by independent assessment by multiple clinicians using DSM-IV criteria (Nigg et al., 2010; 2008; Wang et al., 2008d). Nigg et al. (2010; 2008) found an association between concurrent blood Pb level and ADHD diagnosis in relatively small (n = 150, 236) groups of children ages 6-17 years from the same community, with controls selected from healthy children who responded to community advertisements. Wang et al. (2008d) found an association in a larger (n = 1,260) group of children in China, with controls selected from children attending the same pediatric clinic for respiratory infections.

Braun et al. (2006) found an association in children ages 4-15 years participating in NHANES 1999-2002. ADHD was ascertained by parent-report of ADHD diagnosis or use of stimulant medication, which is subject to reporting bias; however, the examination

of multiple risk factors and outcomes in NHANES reduces the likelihood of biased participation and reporting of ADHD by parents of children with higher Pb exposure. NHANES is not a random sample, but a strength over other studies that examined the prevalence of ADHD diagnosis is the large (n = 4,704) sample size and the nationally-representative results produced with adjustment for sampling weights in models. Surveillance data indicate that states with a higher percentage of children with blood Pb levels ≥ 10 µg/dL have lower prevalence of diagnosed ADHD (CDC, 2012, 2011b). These data reduce the potential for confounding of associations observed in the NHANES population by regional differences in blood Pb levels and ADHD prevalence.

With respect to blood Pb levels associated with ADHD diagnosis, analyses of the concentration-response relationship indicated monotonic increases in ORs across blood Pb level groups (Wang et al., 2008d; Braun et al., 2006). In the analysis of children in NHANES, compared to children with concurrent blood Pb level <0.8 µg/dL, children with concurrent blood Pb level >2.0 µg/dL (maximum not reported) had higher prevalence of ADHD with an OR of 4.1 (95% CI: 1.2, 14.0). A similar OR was estimated for children with blood Pb levels 2.0-5.0 µg/dL (Braun et al., 2006). In the study of children in China, the highest OR was found in children with concurrent blood Pb levels ≥ 10 µg/dL but also was elevated in the group with blood Pb levels 5-10 µg/dL (OR: 4.92 [95% CI: 3.47, 6.98] compared with children with blood Pb level <5 µg/dL) (Wang et al., 2008d). Other evidence indicated associations at lower blood Pb levels, i.e., population means ~1 µg/dL or group with levels >0.8 µg/dL (Nigg et al., 2010; 2008; Braun et al., 2006). However, the examination of adolescents adds uncertainty regarding the relative contributions of higher past Pb exposures and current exposures to the observed associations. Blood Pb levels are higher in early childhood, and among children participating in NHANES who were born 1984-1998, some likely had higher early-life Pb exposures from the use of leaded gasoline in the U.S. (Braun et al., 2006).

Consideration for potential confounding varied among studies. In three-way analyses of covariance, Nigg et al. (2008) adjusted for sex and household income, and Nigg et al. (2010) adjusted for maternal IQ and prenatal smoking exposure. However, in preliminary analyses, Nigg et al. (2010) considered blood hemoglobin, household income, age, sex, and race/ethnicity as potential confounding factors. The analysis of children participating in NHANES adjusted for age, race, prenatal smoking exposure, postnatal smoker in the home, preschool/child care attendance, health insurance coverage, and ferritin levels but initially considered poverty to income ratio, birth weight, and admission to the neonatal intensive care unit (Braun et al., 2006). The results for children in China were adjusted for similar covariates and also family (parent and sibling) history of ADHD diagnosis, ascertained from clinical records (Wang et al., 2008d). Family history of ADHD was selected as a covariate based on its association with child ADHD; no information was

provided on its association with child blood Pb level. None of the studies of ADHD prevalence considered potential confounding by current parental caregiving quality.

In recent commentaries to studies reporting associations between blood Pb level and ADHD in children, Brondum (2011, 2007) asserted the need for studies to consider confounding by parental history of ADHD. Given the highly heritable nature of ADHD, parental ADHD is a strong risk factor for ADHD in children (Faraone and Doyle, 2001); however, data have not characterized well associations of parental history of ADHD and blood Pb level in the child. Therefore, it is uncertain whether the lack of adjustment for parental history of ADHD produces spurious associations between blood Pb level and ADHD in children. Further, because parental history of ADHD likely explains a large portion of variance in child ADHD, not removing that variance with statistical adjustment may mask the smaller magnitude of risk due to other factors, including Pb, not produce spurious associations. Studies that examined parenting behaviors in parents with current ADHD have indicated that parents with ADHD show negative parenting control, i.e., over-reactive disciplining, lack of planning, and disorganization but have not consistently indicated that parents with ADHD have poorer emotional responsiveness, i.e., involvement with the child (as reviewed in Johnston et al., 2012). Thus, the potential for parental ADHD to produce spurious associations between child blood Pb level and child ADHD is not well characterized.

5.3.3.5 Integrated Summary of Attention-related Behavioral Problems

Although not examined as extensively as cognitive function, epidemiologic studies have found associations of childhood blood and tooth Pb levels with attention-related behavioral problems in children and young adults, with more compelling evidence for increases in inattention and impulsivity than hyperactivity, ratings of ADHD-related behaviors, or ADHD diagnosis. The evidence for inattention and impulsivity is provided by both prospective and cross-sectional studies, whereas evidence for hyperactivity, ratings of ADHD-related behaviors, and ADHD diagnosis is provided primarily by cross-sectional studies. With analysis of earlier childhood blood or tooth Pb levels and later childhood behavioral problems, the prospective studies better characterized the temporal sequence between exposure and outcome. In cross-sectional associations with concurrent blood Pb levels, there is greater uncertainty regarding the potential for reverse causation. Associations between blood or tooth Pb levels and attention-related behavioral problems were found in diverse populations in North America, Europe, Asia, Australia, and New Zealand. Most studies had population-based recruitment from prenatal clinics, hospitals at birth, or schools and had moderate to high participation. A few prospective studies had increased loss-to-follow-up in certain groups, for example, lower SES, lower earlier

FSIQ, lower HOME score. This potential selection bias can reduce the generalizability of findings to the original study population, but there was not strong indication that participation was biased to those with higher blood Pb levels and greater attention-related behavioral problems. Multiple testing was common; however, in most studies, the consistent pattern of association observed across the ages of blood Pb level and/or behavior examined increases confidence that the evidence is not unduly biased by the increased probability of finding associations by chance alone.

A large evidence base indicates associations of blood and tooth Pb levels with inattention and impulsivity as assessed using neuropsychological tests or ratings by parents or teachers (Section 5.3.3.1). Observations of associations across the various methods of assessment increase confidence that the collective evidence is not unduly influenced by biased reporting of inattention by parents of children with higher blood Pb levels. Most studies that examined inattention with the CPT found associations with blood Pb level (Figure 5-10 and Table 5-11), including prospective studies, which indicated increases in commission and omission errors or reaction time in association with higher prenatal (maternal) and earlier childhood (age 3-60 month average, age 78 month) blood Pb levels in the Cincinnati cohort at ages 15-17 years (Ris et al., 2004) and with higher tooth Pb (from ages 5-8 years) levels in Boston-area young adults at ages 19-20 years (Bellinger et al., 1994a). Results from prospective studies also indicated higher parental and teacher ratings of inattention in association with higher lifetime average blood Pb levels in children ages 11-3 years in Port Pirie, Australia (Burns et al., 1999) and with tooth Pb levels (from ages 6-8 years) in children ages 8-13 years in New Zealand, and Boston, MA (Fergusson et al., 1993; Leviton et al., 1993). The mean blood Pb levels (prenatal cord, early childhood, lifetime average) in these populations were 7-14 µg/dL. In children, inattention was associated with biomarkers of Pb exposure representing several different lifestages and time periods. Prospective studies did not examined a detailed blood Pb history, and results do not identify an individual critical lifestage, time period, or duration of Pb exposure associated with inattention in children. Associations in prospective studies with tooth Pb level, earlier childhood average and lifetime average blood Pb levels point to an effect on inattention of cumulative childhood Pb exposure. Indicators of more recent Pb exposures were not examined. Evidence did not strongly indicate associations between concurrent blood Pb levels and inattention ratings in the Rochester and Yugoslavia cohorts (Canfield et al., 2003b; Wasserman et al., 2001). This latter group of studies examined lower blood Pb levels, means 6.5 µg/dL, but younger children ages 4-5 years, in whom behaviors may be less reliably measured.

An additional strength of the prospective studies was their more extensive consideration for potential confounding. Although the specific factors varied by study, prospective studies of inattention adjusted for factors such as SES, parental IQ, maternal education,

HOME score, self drug use, prenatal drug and alcohol exposure, and birth outcomes. Adjustment for SES is difficult as it is highly correlated with Pb exposure and there is no single measure that represents SES. Residual confounding also is likely by factors not considered. The combination of evidence from prospective studies that considered several well-characterized potential confounding factors plus coherence with evidence that Pb exposure induces impulsivity in animals increase confidence that the associations between blood and tooth Pb levels and inattention and impulsivity observed in children represent a relationship with Pb exposure.

Several recent cross-sectional studies provided evidence of associations of higher concurrent blood Pb level with increases in impulsivity using response inhibition tests and higher inattention ratings in children ages 8-17 years. These associations were found in populations with mean concurrent blood Pb levels 1 and 4 µg/dL (Nicolescu et al., 2010; Nigg et al., 2008). However, the contribution of higher Pb exposures earlier in childhood cannot be excluded. Further, while these recent studies considered potential confounding by parental education, they had less consistent consideration for other SES-related factors or parental caregiving quality than prospective studies. Some considered parental history of psychopathology (Cho et al., 2010; Nicolescu et al., 2010); however, its relationship with parental caregiving quality is not well characterized. Recent cross-sectional studies that included younger children (ages 3-5 years) also found associations between concurrent blood Pb level and higher inattention as rated by teachers or study examiners (Plusquellec et al., 2010; Roy et al., 2009a); however, ratings in young children may be less reliably measured. With the exception of the Rochester cohort study (Canfield et al., 2003b), several studies found associations between blood Pb level and inattention with adjustment for child IQ (Cho et al., 2010; Nigg et al., 2008; Silva et al., 1988), supporting an effect of Pb exposure on inattention independent of effects on cognitive function.

The epidemiologic findings for impulsivity are supported by observations in rats and monkeys of Pb-induced impaired response inhibition in tests of discrimination reversal learning and FR/waiting for reward (Stangle et al., 2007; Brockel and Cory-Slechta, 1998; Rice and Gilbert, 1985). Coherence is found particularly with associations found between blood Pb levels and impaired response inhibition in children as assessed using the stop signal task. Impulsivity in animals was found with early postnatal (lactation) and lifetime dietary Pb exposures relevant to humans, i.e., resulting in blood Pb levels 11-31 µg/dL. The effects of early postnatal Pb exposure are consistent with the continuing development of the nervous system and greater Pb absorption and retention during early life. The findings in children and animals for Pb-associated impulsivity are supported by observations that Pb affects dopaminergic neurons of the frontal cortex and striatum of the brain by altering dopamine release and receptor density. The circuitry in

these regions is thought to mediate response inhibition. In animals, the effects of Pb on sustained attention have been inconsistent; however, studies find Pb-induced increases in distractibility. Attention-related behavioral problems also have been linked with changes in the hippocampus, and evidence describing the effects of Pb on hippocampal functions further supports the mode of action for Pb-associated increases in attention-related behavioral problems.

Although examined in fewer studies, hyperactivity has been linked with higher blood and tooth Pb levels in children (Section 5.3.3.2). Previous findings were limited to cross-sectional and case-control studies. However, a recent prospective study found higher teacher ratings of hyperactivity in children in the U.K. ages 7-8 years with age 30 month blood Pb levels >10 µg/dL, with adjustment for maternal education and smoking, SES, home facilities score, family adversity index, plus other factors (Chandramouli et al., 2009). Among cross-sectional studies, associations were found with adjustment for SES and maternal education; however, parental caregiving quality was examined infrequently.

Recent studies also found associations with higher parental ratings of a composite index of ADHD-related behaviors, including a large NHANES analysis that used DSM-IV criteria (Froehlich et al., 2009). In the few available studies, concurrent blood Pb levels were associated with prevalence of diagnosed ADHD in children (Section 5.3.3.4). There is coherence with evidence from prospective studies for associations of blood and tooth Pb levels with inattention, hyperactivity, and impulsivity, which comprise ADHD. However, the small number of studies, their cross-sectional or case-control design, and lack of consideration for potential confounding by parental caregiving quality preclude conclusions regarding the relationship between Pb exposure and ADHD specifically.

5.3.4 Conduct Problems

5.3.4.1 Epidemiologic Studies of Conduct Problems in Children

The 2006 Pb AQCD (U.S. EPA, 2006b) described several prospective studies that demonstrated associations of higher blood, tooth, and bone Pb levels with conduct problems in children as rated by parents or teachers [(U.S. EPA, 2006b), and see Table 5-12 from this ISA]. A few previous studies found associations with criminal offenses in adolescents or young adults. Supporting evidence from recent prospective studies included follow-up of previous cohorts to older ages (Table 5-12). Recent cross-sectional studies found associations between concurrent blood Pb level and ratings of misconduct, but several had limitations aside from establishing temporality, including prenatal drug and alcohol exposure, treatment with chelators earlier in childhood, and less extensive

consideration for potential confounding. Previous studies found associations with mean blood Pb levels >10 µg/dL. Recent evidence indicated associations with lower blood Pb levels, means 1-8 µg/dL. However, in these children and young adults, the influence of higher Pb exposures earlier in childhood cannot be excluded. In the evaluation of epidemiologic evidence for conduct problems, greater emphasis was placed on evidence from prospective studies and studies with greater consideration for potential confounding.

Table 5-12 Associations between blood Pb level and misconduct in children and young adults.

Study[a]	Study Population and Methodological Details	Blood (µg/dL), Tooth or Bone (µg/g) Pb Levels	Outcome	Effect Estimate (95% CI)[b]
Prospective Studies of Ratings of Misconduct				
Dietrich et al. (2001)	195 children followed from birth (1979-1985) to age 15-17 yr, Cincinnati, OH Recruitment at prenatal clinic. High follow-up participation, no selective attrition. Primarily African American. Linear regression model adjusted for HOME score, parental IQ, current SES, birth weight. Also considered potential confounding by maternal age, other birth outcomes, prenatal smoking, alcohol use, and marijuana use, Fe status, ear infections, sex, age, caregiver education, public assistance, attendance at preschool program, # children and adults in home.	0-6 yr avg blood: NR	Self-Report of Delinquent Behavior Score Parental Report of Predelinquent and Delinquent Behavior Score at ages 15-17 yr	0.10 (0.01, 0.193) 0.09 (-0.02, 0.20)
Burns et al. (1999)	322 children followed from birth (1979-1982) to age 11-13 yr, Port Pirie, Australia. Moderate follow-up participation. Participants had higher birth weight, older mothers, less educated fathers. Log linear regression model adjusted for maternal age, prenatal smoking status, birth weight, type of feeding, length of breastfeeding, maternal education, IQ, and concurrent psychopathology, paternal education, birth order, family functioning, paternal occupation, parent smoking, marital status, HOME, child IQ. [a]Results are organized according to outcome category, behavior ratings then documented criminal offenses. Within each category, studies are organized by strength of design and analysis.

[b]Unless otherwise specified, effect estimates are standardized to a 1 µg/dL increase in blood Pb level or 1 µg/g increase in bone or tooth Pb level in the interval from the 10th percentile to 10 µg/dL blood Pb or bone Pb or the 90th percentile, whichever is lower.

[c]Odds in higher quantile of blood or bone Pb level compared to that in lowest quantile of blood or bone Pb level (reference).
[d]95% CI was estimated from a reported p-value of 0.05.

Prospective studies provided key evidence for associations of earlier childhood and lifetime average blood Pb levels and tooth Pb levels (from age 6-8 years) with conduct problems such as delinquent behavior, aggression, antisocial activities, and destructive behavior as rated by parents and/or teachers in children ages 8-17 years (Table 5-12). These studies had moderate to high follow-up participation that was not conditional on blood Pb levels, reducing the likelihood of selection bias. Across studies, behaviors were assessed using various tests, but several studies used the Child Behavior Checklist. Associations were found with both parent and teacher ratings, increasing confidence that biased reporting of conduct problems by parents of children with higher Pb exposures did not unduly influence the collective body of evidence. The evidence from prospective studies is substantiated by associations observed in diverse populations (i.e., U.K., Cincinnati, Port Pirie, Australia) that considered several potential confounding factors including multiple SES-related factors, parental caregiving quality, smoking exposure, and birth outcomes (Chandramouli et al., 2009; Dietrich et al., 2001; Burns et al., 1999). In the Yugoslavia cohort, lifetime average blood Pb level was associated with parent ratings of aggressive and delinquent behavior with consideration for similar potential confounding factors but in children from ages 4-5 years, in whom behaviors may be less reliably measured or predictive of behavior at older ages (Wasserman et al., 2001).

Collectively, the evidence from prospective studies indicated associations of teacher and parental ratings of aggressive, destructive, antisocial, and delinquent behavior with measures of cumulative Pb exposure, i.e., age 0-6 year average blood, lifetime average blood, tooth, and bone Pb level. Associations with tooth (Bellinger et al., 1994b) and bone (Needleman et al., 1996) Pb level, collected prior to or at the same time as behavior assessment, respectively, were found with adjustment for several potential confounding factors as noted above, with the exception of parental caregiving quality. Collective evidence from prospective studies most clearly indicated associations between blood Pb level and ratings of conduct problems with population mean or group blood Pb levels ≥ 10 µg/dL (Chandramouli et al., 2009; Dietrich et al., 2001; Wasserman et al., 2001; Burns et al., 1999). Among children ages 7-8 years in the U.K. born in the 1990s, Chandramouli et al. (2009) recently found that compared with children with age 30 month blood Pb levels 0-2 µg/dL, children with blood Pb levels >10 µg/dL had increased odds of greater antisocial activities as rated by parents or teachers with an OR of 2.9 (95% CI: 1.05, 8.0). The Boston cohort was found to have lower childhood blood Pb levels (Table 5-3); however, tooth Pb level was associated with a higher total externalizing behavior score, which also included inattention (Bellinger et al., 1994b).

As described above, cross-sectional studies also indicated blood Pb-associated higher ratings of conduct problems; however, because of their various limitations discussed below, their results were less of a consideration in drawing conclusions about the effects of Pb exposure on conduct problems. In the recent analysis of 2,867 children ages 8-15 years participating in NHANES 2001-2004, Braun et al. (2008) analyzed blood Pb level as a categorical variable and found higher prevalence of conduct disorder as ascertained by parental questionnaire with concurrent blood Pb levels in the range of 0.8 to 1.0 µg/dL. Compared with children with blood Pb levels <0.8 µg/dL, the OR in children with blood Pb levels 0.8-1.0 µg/dL was 7.24 (95% CI: 1.06, 49.5). The wide 95% CIs likely were due to the small numbers of cases of conduct disorder. For example, there were 22 children rated as having conduct disorder in the group with blood Pb levels 0.8-1.0 µg/dL. Nigg et al. (2008) found a blood Pb-associated higher rating (parent or teacher) of oppositional defiant disorder in a population with similarly low concurrent blood Pb levels, means ~1 µg/dL. However, the implications are limited because of the case-control design (Section 5.3.3.4) and lack of consideration of potential confounding factors. Further, because these studies examined adolescents who likely had higher earlier childhood Pb exposures, there is uncertainty regarding the level, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

Consideration for potential confounding varied among the cross-sectional studies of conduct problems. With the exception of Nigg et al. (2008), most considered SES. However, only a few considered parental caregiving quality (i.e.,. HOME score) or current maternal psychopathology. An analysis of children in Baltimore, MD adjusted results for current maternal depressive symptoms but examined children less than age 5 years and analyzed misconduct as a component of total behavior problem score, which included internalizing behaviors (Sciarillo et al., 1992). Chiodo et al. (2007) found that higher concurrent blood Pb level was associated with higher teacher ratings of social problems and delinquent behavior in children ages 7 years in Detroit, MI with adjustment for HOME score and initial consideration of current maternal psychopathology; however, the study population had high prevalence of prenatal drug and alcohol exposure. Neither of these exposures met the criteria for inclusion in the model, indicating lack of confounding by these factors. Nonetheless, the results may not be representative of the general U.S. population of children. Lack of representativeness also may pertain to the results of Chen et al. (2007), who examined children who were given chelators at ages 1-3 years because of high earlier childhood blood Pb levels (20-44 μg/dL).

While few in number, evidence from prospective studies also indicated associations of biomarkers of earlier childhood Pb exposure with delinquent and criminal acts as objectively assessed from government records. These studies of delinquent and criminal acts examined Pb levels in blood or tooth samples collected in the 1980s when Pb exposures were much higher than those of the current U.S. population (Fergusson et al., 2008; Wright et al., 2008). However, the prospective study design and consideration for several potential confounding factors increase confidence that the observed associations represent a relationship with Pb exposure.

In the Cincinnati cohort, prenatal cord and age 0-6 year average blood Pb levels were associated with self- and parent-reported delinquent and social acts at ages 16-17 years (Dietrich et al., 2001). Wright et al. (2008) recently extended these findings to include associations of prenatal cord and age 6 year blood Pb levels with criminal and violent criminal arrests at ages 19-24 years. In models that adjusted for maternal IQ, sex, SES score, and maternal education, the relative risks (RRs) for total arrests per 1 μg/dL increment in blood Pb level were 1.07 (95% CI: 1.01, 1.13) for prenatal blood Pb level, 1.01 (95% CI: 0.97, 1.05) for age 0-6 year average blood Pb level, and 1.05 (95% CI: 1.01, 1.09) for blood Pb level at age 6 years. Interactions terms for blood Pb by sex were not statistically significant; however, the attributable risk was considerably higher for males (0.85 arrests/year [95% CI: 0.48, 1.47]) than for females (0.18 [95% CI: 0.09, 0.33]). A strength of Wright et al. (2008) was the detailed examination of potential confounding by a large number of variables (Table 5-12). All of the examined covariates were weakly correlated with blood Pb levels (r = 0.24-0.35), thereby reducing the

potential for confounding by the examined factors. Nonetheless, variables such as maternal IQ, maternal education, and SES were included in the model because they were associated with arrests in the full multivariate model or changed the blood Pb level estimate by more than 10%. HOME score was similar between subjects with and without criminal arrest records and did not meet the criteria for inclusion in final models.

The study of the New Zealand cohort also considered several potential confounding factors such as family functioning and parental bonding (Table 5-12) (Fergusson et al., 2008). Per 1 μg/g Pb in teeth obtained between ages 6 and 8 years, there was a 0.49 (95% CI: 0.16, 0.82) increase in the number of documented violent or property convictions at ages 14-21 years. Results were adjusted for SES, ethnicity, maternal education, family conflict, prenatal smoking exposure, physical abuse in childhood, and parental alcoholism. The effect estimate for tooth Pb level decreased in adjusted models and was found to account for <1% in the variance of criminal convictions; however, the association remained statistically significant.

The epidemiologic studies described above employed different designs and assessed conduct problems using different behaviors and methods. The consistency of association of Pb biomarker levels with conduct problems was corroborated in a recent meta-analysis (Marcus et al., 2010) that included 19 studies (several of which are described above) with a total of 8,561 children and adolescents (mean ages ranging from 3.5 years to 18.4 years). Effect estimates were converted to Pearson correlation coefficients, and the combined effect estimate was r = 0.19 (95% CI: 0.14, 0.23). The key finding of this study was the robustness of associations to between-study sources of heterogeneity. In the meta-analysis, effect sizes did not differ significantly between prospective and cross-sectional studies, among studies that examined different conduct problems (i.e., opposition defiance, delinquency, externalizing problems), or among studies that assessed conduct disorders using self-report, teachers report, or criminal records. Adjustment for covariates such as SES, birth weight, parental IQ, and home environment did not attenuate the relationship between blood Pb level and conduct problems. In addition to strengthening the evidence for the independent associations of Pb biomarker levels with conduct problems, the results indicated that the lack of adjustment for any particular covariate, including HOME score, does not warrant limiting inferences from a particular study. The major source of heterogeneity in effect estimates was the biomarker of Pb examined. A larger magnitude of effect was estimated for hair Pb levels compared with bone or blood Pb levels, which had similar effect sizes. The authors suggested that hair Pb may be a better indicator of cumulative Pb exposure compared to bone Pb levels due to the high turnover of bone throughout childhood and into adolescence; however, an empirical basis for interpreting hair Pb measurements in terms of body burden or exposure has not been firmly established (Section 4.3.4.2).

Several studies of misconduct aimed to characterize whether associations with biomarkers of Pb exposure were independent of effects on IQ and educational attainment. Most studies found that associations of Pb biomarkers with conduct problems remained statistically significant in a model that additionally adjusted for child IQ or educational attainment, indicating that Pb exposure may have a direct effect on misconduct independent of its effect on cognitive function (Chandramouli et al., 2009; Fergusson et al., 2008; Burns et al., 1999). However, simple statistical adjustment for cognitive function indices may result in an underestimate of the effect on misconduct because a decrement in cognitive function may lie on the causal pathway to behavioral problems. Chen et al. (2007) used path analysis to characterize the direct effects and indirect effects (mediated through child IQ) of blood Pb level on total externalizing problem ratings at age 7 years; however, results were inconsistent. A direct effect was estimated for externalizing problems rated by teachers, and an indirect effect was estimated for problems rated by parents (Table 5-12). These findings may have limited applicability to the general U.S. population given that some children in the study had been treated with chelators at ages 1-3 years because of high blood levels, and it is uncertain whether the observed associations were due to the residual effect of high earlier blood Pb levels (20-44 µg/dL).

5.3.4.2 Toxicological Studies of Aggression

While recent studies were not identified, evidence available in the 2006 Pb AQCD (U.S. EPA, 2006b) pointed to the effects of Pb on changes in social behavior in rodents and nonhuman primates. Most observations comprised Pb-induced increases in social and sexual investigation, as indicated by sniffing, grooming, following, mounting, and lordosis behavior. In animals, the social behavior most comparable to epidemiologic findings in children is aggression; however, the effects of Pb on aggression in animals were inconsistent. In animals, aggression was assessed as threats, attacks, bites, chases, and offensive posture in encounters with other animals, and Pb exposure was found to not affect, decrease, and increase aggression. Pb exposure generally was not found to affect aggression in juvenile animals; however, increased aggression was found in adult animals with high concentration (>2,500 ppm) gestational plus postnatal dietary Pb exposure.

Delville (1999) found Pb-induced increases in aggression with the lowest concentration Pb exposure examined among all animal studies. Golden hamsters exposed to 100 ppm Pb acetate GD8-PND42 in drinking water had blood Pb levels of 10 to 15 µg/dL at PND42. As adults at PND45, Pb-exposed animals displayed more aggression as measured by attacking and biting an intruder put in the cage. In mice, higher Pb exposure produced mixed findings. BK:W mice exposed to 1,300 ppm Pb acetate in drinking water

from gestation through age 18 weeks displayed increased social and sexual investigation but not aggression in males (femur Pb level at 18 weeks: 5,364 μM Pb/g ash) or females (femur Pb level at 18 weeks: 4,026 μM Pb/g ash) (Donald et al., 1986). Additional investigation from the same laboratory exposed BK:W mice to 2,500 ppm Pb acetate in drinking water from gestation through age 17-18 weeks, and found shorter latencies to aggression in Pb-exposed mice than in controls (Donald et al., 1987). In juvenile Long Evans hooded rats, lactation-only (PND1-PND21) exposure to 670 ppm Pb chloride in drinking water increased "rough and tumble" play behavior at PND36 which was not characterized as aggression because of the lack of injury, submissive posturing, or escape attempts in encounters with other animals (Holloway and Thor, 1987).

5.3.4.3 Summary of Conduct Problems

Although not examined as extensively as cognitive function, previous and recent prospective studies consistently demonstrate Pb-associated increases in delinquent behavior, aggression, antisocial activities, and destructive behavior as rated by parents and teachers in children and as assessed with government records of criminal offenses in adolescents and young adults (Table 5-12). Most studies examined multiple behaviors; however, the consistent pattern of association observed across the ages of blood Pb level and/or behaviors examined increases confidence that the evidence is not unduly biased by an increased probability of associations by chance alone. Recent cross-sectional studies found associations between concurrent blood Pb level and ratings of misconduct, but several had additional limitations aside from study design, including prenatal drug and alcohol exposure, treatment with chelators, or limited consideration for potential confounding (Nigg et al., 2008; Chen et al., 2007; Chiodo et al., 2007). The most informative cross-sectional study was that finding a 7.24 (1.06, 49.47) higher odds of conduct disorder in adolescents ages 8-15 years participating in NHANES with concurrent blood Pb levels 0.8-1.0 μg/dL compared with blood Pb levels <0.8 μg/dL with adjustment for age, sex, race, poverty to income ratio, and smoking exposure (Braun et al., 2008). However, the association was imprecise and could have been influenced by higher past Pb exposures of the adolescents. Further, potential confounding by parental caregiving quality was not examined. Evidence of Pb-induced aggression in animals was mixed in adult animals with lifetime Pb exposure beginning in gestation and not indicated in juvenile animals.

The evidence in children from prospective studies is substantiated by analyses of school-aged children (ages 8-17 years) in populations from various locations and SES (i.e., U.K., Cincinnati, Port Pirie, Australia) with high participation rates, lack of indication of substantial selection bias, and consideration of several potential confounding factors

including multiple SES-related factors, parental caregiving quality, smoking exposure, and birth outcomes (Chandramouli et al., 2009; Dietrich et al., 2001; Burns et al., 1999). Pb biomarker levels were associated with both parent and teacher ratings of conduct problems, reducing the likelihood of biased reporting of conduct problems by parents of children with higher Pb biomarker levels. Recent prospective studies of criminal offenses in young adults, ages 19-24 years, strengthened previous evidence with consideration for potential confounding by factors such as SES, smoking, drug, and alcohol exposure, and parental caregiving quality (Fergusson et al., 2008; Wright et al., 2008). In the Cincinnati cohort, a 1 µg/dL increase in age 6 year blood Pb level was associated with an increased risk of total arrests with an RR of 1.05 (95% CI: 1.01, 1.09) with adjustment for maternal IQ, sex, SES, and maternal education (Wright et al., 2008). In the New Zealand cohort, a 1 µg/g Pb in teeth obtained between ages 6 and 8 years was associated with a 0.49 (95% CI: 0.16, 0.82) increase in the number of documented violent or property convictions at ages 14-21 years (Fergusson et al., 2008) with adjustment for SES, ethnicity, maternal education, family conflict, prenatal smoking exposure, physical abuse in childhood, and parental alcoholism. Further support for Pb-associated increases in conduct problems was provided by a recent meta-analysis that found that evidence was robust to heterogeneity in study design, definition and assessment method of conduct problems, potential confounding variables examined, and population mean blood Pb levels (Marcus et al., 2010).

Associations of conduct problems (parent/teacher ratings and criminal offenses) with earlier childhood blood (e.g., age 30 month, age 6 year), early childhood average blood (e.g., age 0-6 year), lifetime average blood (to age 11-13 years), tooth, and bone Pb levels pointed to the effects of early childhood or cumulative Pb exposures. Associations were found with a mean lifetime (to age 11-13 years) average blood Pb level of 14 µg/dL, mean age 6 year blood Pb level of 6.8 µg/dL, and age 30 month blood Pb levels >10 µg/dL. Recent cross-sectional studies found associations with concurrent blood Pb level and lower blood Pb levels, means 1-8 µg/dL, but the study limitations detailed above limit inferences regarding the effects of Pb exposure on conduct problems in these populations. Most prospective studies did not analyze Pb biomarker levels at multiple lifestages and time periods, including later childhood and more recent adult exposures, or examine differences in association between Pb exposures at various lifestages and time periods. The evidence does not identify an individual critical lifestage, time period, or duration of Pb exposure associated with conduct problems in children or exclude an effect of more recent Pb exposures.

5.3.5 Internalizing Behaviors in Children

5.3.5.1 Epidemiologic Studies of Internalizing Behaviors in Children

A majority of investigations of the effects of Pb on behavior in children has focused on externalizing behaviors such as inattention, hyperactivity, aggression, and delinquency. However, several studies also have linked biomarkers of Pb exposure in children with internalizing behaviors characterized by directing feelings and emotions inward, i.e., withdrawn behavior, symptoms of depression, fearfulness, and anxiety. Whereas some studies found stronger associations for externalizing behaviors than for internalizing behaviors (Plusquellec et al., 2010; Wasserman et al., 2001; Bellinger et al., 1994a; Sciarillo et al., 1992), others did not find a clear difference in the strength of association (Roy et al., 2009b; Chiodo et al., 2004; Bellinger et al., 1994b). Internalizing behaviors were assessed frequently using the Child Behavior Checklist, and as with attention-related behavioral problems and conduct problems, were rated by parents and/or teachers. Associations with both parent and teacher ratings increase confidence that biased reporting of internalizing behaviors by parents of children with higher blood Pb levels did not unduly influence the collective body of evidence. Most studies had moderate to high follow-up participation. With the exception of the Yugoslavia cohort, participation was not biased to higher blood Pb levels. Additionally, in most studies, a consistent pattern of association was observed across the ages of blood Pb level and/or multiple behaviors examined, which increases confidence that the evidence is not strongly biased by an increased probability of associations found by chance alone.

Key evidence was provided by prospective studies in various populations, i.e., Boston, Port Pirie, Australia, and Yugoslavia. Collectively, these studies found higher ratings for internalizing behaviors in children (n = 322-1,511, ages 3-13 years) in association with concurrent blood Pb level, lifetime average blood, and tooth Pb levels (Wasserman et al., 2001; Burns et al., 1999; Wasserman et al., 1998; Bellinger et al., 1994b). In the Port Pirie cohort, Burns et al. (1999) found that higher lifetime average blood Pb levels (mean: ~14 µg/dL) were associated with parental ratings of externalizing behaviors more strongly in boys and with internalizing behaviors (i.e., withdrawn, anxious/depressed) more strongly in girls ages 11-13 years, which may indicate sex differences in the effect of Pb or differences in the types of behaviors that are observed and reported in girls versus boys. Based on a log-linear model, a 1 µg/dL increase in lifetime average blood Pb level was associated with increased odds of an anxious/depressed rating above the median of 1.04 (95% CI: 1.0, 1.09) among 159 boys ages 11-13 years (in the 10th-90th percentile interval of blood Pb level 13.7-14.9 µg/dL) and 1.08 (95% CI: 1.01, 1.15) among 163 girls ages 11-13 years (in the 10th-90th percentile interval of blood Pb level).

These associations were found with the adjustment for factors related to SES and parental caregiving including HOME score, family functioning score, and current maternal psychopathology (General Health Questionnaire).

Differences between externalizing and internalizing behaviors also were found in the Yugoslavia cohort according to age of assessment and blood Pb levels. This cohort was examined between ages 3 and 5 years, ages at which behaviors may be less reliably assessed. Among 379 children ages 3 years from the higher and lower Pb exposure towns, higher cord and concurrent blood Pb levels were associated with higher maternal ratings of anxious-depressed, withdrawn, and externalizing behaviors, with stronger associations found for concurrent blood Pb level (mean: 25.8 µg/dL) (Wasserman et al., 1998). Among 191 children ages 4-5 years from the lower Pb exposure town, higher lifetime average blood Pb level (mean: 9.6 µg/dL), was associated with higher ratings of delinquent behavior and internalizing behaviors, with stronger associations found for delinquent behavior (Wasserman et al., 2001). A log unit increase in higher lifetime average blood Pb level was associated with a 0.22 log (95% CI: -0.04, 0.47) higher rating of withdrawn behavior and 0.19 log (95% CI: -0.05, 0.43) higher rating of anxious-depressed behavior in children at ages 4-5 years. Results at each age were adjusted for age, sex, HOME score, and maternal education. Results at age 3 years and 4-5 years were additionally adjusted for residence type and maternal history of smoking, respectively.

With regard to important lifestages or durations of Pb exposure, results from prospective studies did not clearly demonstrate differences in association among biomarkers measured at various lifestages or time periods. The importance of childhood cumulative exposure was indicated by associations with lifetime average blood Pb levels in the Port Pirie cohort (to age 11-13 years) and in the Yugoslavia cohort (to age 5 years) and with tooth Pb (from age 6 years) levels in the Boston cohort at age 8 years. In the Boston cohort, Pb levels measured in teeth (mean: 3.4 µg/g) but not cord blood were associated with a higher teacher rating of internalizing behaviors at age 8 years (Bellinger et al., 1994b). In another Boston-area cohort, tooth (collected at first or second grade) Pb levels were not associated with self-rated symptoms of depression (Profile of Mood States questionnaire) at ages 19-20 years (Bellinger et al., 1994a). Prospective studies did not analyze a detailed history of Pb biomarker levels to evaluate persistence of effects of early exposure or to identify an individual critical lifestage or time period of Pb exposure associated with increases in internalizing behaviors. The available evidence does not preclude an effect of later childhood or more recent Pb exposure.

In the Cincinnati cohort, using structural equations, Dietrich et al. (1987b) found that the associations of prenatal maternal and infant age 10 day blood Pb level (respective means: 8.3 and 4.9 µg/dL) with poorer mood in infants (n = 185) ages 6 months were indirect,

meaning they were mediated through lower birth weight and/or shorter gestation. These results suggested that Pb may exert its effects by impairing nervous system development. The fetal period is an active period for neuronal differentiation, dendritic branching, and synaptogenesis, which if impaired by Pb exposure, could have broad implications on a wide range of subsequent neurodevelopmental effects. There are few such analyses, and the findings are limited by the lower reliability of mood assessed in infancy.

Cross-sectional studies found associations between concurrent blood or hair Pb levels and teacher and parent ratings of internalizing behaviors in children. Associations were found in children ages 3-16 years (n = 303-756) in China and India with mean concurrent blood Pb levels 9-14 µg/dL (Liu et al., 2011b; Bao et al., 2009; Roy et al., 2009a). Results were adjusted for family income and parental education but not caregiving quality. In the few studies of populations with mean blood Pb levels ~5 µg/dL, results were inconsistent. Chiodo et al. (2004) found an association with internalizing behaviors with adjustment for child and caregiver life stress and marital status in 246 children age 7 years in Detroit, MI who had high prevalence of prenatal alcohol or drug exposure. HOME score, SES, maternal education, prenatal alcohol exposure, drug exposure were not found to influence associations with blood Pb level; however, the results may lack generalizability to the general population of U.S. children. A study that examined 79-91 Inuit children (age 5 years) in Quebec, Canada, did not find associations between concurrent blood Pb level and internalizing behaviors with consideration of potential confounding by HOME score, caregiver education and IQ, blood Hg levels, and prenatal smoking and alcohol exposure (Plusquellec et al., 2010).

Associations of Pb biomarkers with internalizing behaviors in children were observed with consideration for a wide range of potential confounding factors, most commonly, age, birth outcomes, parental education, and other SES-related factors. Parental caregiving quality was evaluated in few studies. Blood Pb-associated higher ratings of internalizing behaviors were found with adjustment for HOME score in the Yugoslavia cohort (Wasserman et al., 2001; 1998), and HOME, family functioning, and current maternal psychopathology (General Health Questionnaire) in the Port Pirie cohort (Burns et al., 1999). Several studies, each of which adjusted for a different set of covariates, found similar or slightly attenuated effect estimates in univariate and multivariate models (Wasserman et al., 2001; Burns et al., 1999; Bellinger et al., 1994b). Collectively, these observations increase confidence that the observed associations with Pb biomarkers reflect a relationship with Pb exposure.

5.3.5.2 Toxicological Studies of Internalizing Behaviors

As in epidemiologic studies, toxicological studies have focused more on cognitive function and attention-related behavioral problems and less on emotional- and mood-related behaviors. Pb biomarker levels have been associated with ratings of withdrawn behavior, depression, and anxiety in children, and this evidence is supported by findings of Pb-induced anxiety, emotionality and depression-like behaviors in animals.

Emotionality has been indicated by loss of motivation and increased frustration in response to errors and reward emission in visual or olfactory discrimination task trials in Pb-exposed rats (Beaudin et al., 2007; Stangle et al., 2007). In each study, Long-Evans rats were exposed to Pb during and after lactation (300 ppm Pb acetate via dam drinking water PND1-PND17 then either 20 or 300 ppm PND17-PND30 in own water, with respective blood Pb levels of 13 and 31 µg/dL on PND52). In Beaudin et al. (2007), greater disruption in performance (i.e., failure to enter testing alcove) after committing errors and having rewards omitted was found in rats with blood Pb levels 13 and 31 µg/dL tested at age 9-15 weeks. Pb-exposed rats also had greater response latency with reward omission as indicated by the entrance into the testing alcove but failure to respond within a set period of time. In Stangle et al. (2007), increased reactivity to errors and reward omission was found in rats with blood Pb levels 31 µg/dL. Blood Pb levels were measured after a lag period, and peak blood Pb levels in these animals may have been higher than those reported. In rhesus monkeys, emotional dysregulation was indicated by tactile defensiveness after exposure to Pb acetate/50% glucose in 4 cc daily milk formula from PND8 to ages 1-2 years (producing blood Pb 35-40 µg/dL) (Moore et al., 2008).

In other studies, Wistar rats showed emotionality and depression-like behavior in the open field test and forced swim test (i.e., Porsolt's Test) with gestational/lactational Pb exposure (de Souza Lisboa et al., 2005). The open field test monitors activity levels and movements of animals in three dimensions. Depression-like behavior is indicated by freezing behavior and low levels of activity. Emotionality is indicated by grooming or freezing. In the forced swim test, animals are placed in a vertical cylinder of water from which there is no escape and monitored for duration of struggling or attempt to escape. Animals that stop quickly are ascribed a depression-like phenotype. As in many other neurobehavioral tests, sex-specific differences in responses were found. Pb-exposed males showed increased emotionality in the open field test as indicated by fewer counts of rearing. Pb-exposed females showed a depression-like phenotype in the forced swim test as indicated by longer time of immobility (de Souza Lisboa et al., 2005). While measured blood Pb levels of rats were low, 5-7 µg/dL, they were measured after a lag in exposure (PND70) and produced by oral gavage (10 mg/day) of mothers, a route that

may have uncertain relevance to human routes of Pb exposure. Pb-induced immobility in the forced swim test also was found with 6-weeek postnatal Pb exposure via drinking water but producing blood Pb levels 40 µg/dL. Reducing internal Pb dose with the chelator succimer reversed Pb-induced immobility (Stewart et al., 1996).

Depression initially may seem like an unexpected effect of immune modulation, but it has been linked to an interaction between the CNS and the immune system via alterations in cytokines such as IL-6 (Section 5.6.6.1). Dyatlov and Lawrence (2002) found that dietary Pb exposure through lactation and a brief period after weaning (500 µM, PND1-PND22, resultant blood Pb level: 17 µg/dL) potentiated sickness behavior in mice in response to bacterial infection. Sickness behavior was evidenced by an increase in serum IL-6 levels with an accompanying decrease in food and water intake and increase in body weight. This phenotype was correlated with decreases in the populations of several T cell subtypes. Pb exposure also potentiated release of IL1β, which plays an important role in inflammatory responses to infection and has been shown to inhibit hippocampal glutamate release in young but not aged animals. Sickness behavior also was induced in Pb-exposed animals with IL-6 and IL-1 administration without infection, further supporting a role for immunomodulation in mediating sickness behavior.

Pb exposure had mixed effects on anxiety-related responses as measured by the elevated plus maze, which assesses behavior of rodents in an unfamiliar environment. The maze is elevated above the floor and consists of two arms that are enclosed with walls intersected with two arms that have no walls. The animal is placed in the center of the maze, and longer latency to enter an open arm, and lower frequency and duration of entries into an open arm are indicative of anxiety. In a study of gestational/lactational (GD1-PND24) exposure to 2.84 mg/mL Pb acetate trihydrate in drinking water, Sprague-Dawley rats did not differ in anxiety-related responses from controls. Blood Pb levels of Pb-exposed rats were higher than those relevant to humans, 65.8 µg/dL at PND25 (Molina et al., 2011). Another study exposed female rats postnatally (PND1-PND30) to 2,000 ppm Pb acetate in drinking water, which yielded lower blood Pb levels, 34 µg/dL. Pb-exposed rats had an increase in anxiety-related behavior at PND60, as indicated by a lower percentage of open arm entries and less time spent in the open arms (Fox et al., 2010).

5.3.5.3 Summary of Internalizing Behaviors

Internalizing behaviors, i.e., withdrawn behavior, symptoms of depression, anxiety, have been examined less than externalizing behaviors (i.e., attention-related behavioral problems, misconduct). However, several prospective studies found associations of higher parental and teacher ratings of internalizing behaviors with higher tooth or lifetime average blood Pb levels in children ages 8-13 years (Burns et al., 1999; Bellinger et al., 1994b) and higher concurrent and lifetime average blood Pb levels in children ages 3-5 years (Wasserman et al., 2001; 1998). Collectively, the lack of biased participation by subjects with higher blood Pb levels and associations found with both parent and teacher ratings increase confidence that the evidence is not unduly influenced by biased reporting of behaviors by parents of children with higher blood Pb levels. The prospective studies found associations with adjustment for several potential confounding factors, including SES and parental education and caregiving quality. In prospective studies, associations were found with tooth Pb levels and lifetime average and concurrent blood Pb levels. While, there is not a clear indication of an individual critical lifestage or time period of Pb exposure associated with internalizing behaviors, several observations point to an effect of cumulative childhood Pb exposure. These results do not preclude an effect of later childhood or more recent Pb exposures. In prospective studies, associations with internalizing behaviors were found with a mean lifetime average blood Pb levels of 14 µg/dL to age 11-13 years (Burns et al., 1999) and 9.6 µg/dL to age 4.5-5 years (Wasserman et al., 2001). In children ages 4.5-5 years (Yugoslavia cohort), in whom behavioral ratings may be less reliably measured, lifetime average blood Pb level was associated more strongly associated with the rating of delinquent behavior than ratings of internalizing behaviors (Wasserman et al., 2001). Cross-sectional studies provided supporting evidence of concurrent blood Pb-associated increases in internalizing behaviors in children ages 3-16 years, and several considered potential confounding by a similar set of factors as did the prospective studies. However, associations in populations with mean concurrent blood Pb levels ~5 µg/dL were inconsistent.

Evidence in children is supported by observations that dietary Pb exposure (early postnatal to day 22 or 30) resulted in depression-like behavior and emotionality in rodents, (Beaudin et al., 2007; Stangle et al., 2007; Dyatlov and Lawrence, 2002) and rhesus monkeys (postnatal to age 1-2 years) (Moore et al., 2008), with some evidence in rodents at blood Pb levels relevant to humans (13-31 µg/dL). Evidence for Pb-induced anxiety in animals is mixed. Mode of action support is provided by well-documented evidence for Pb-induced changes in the HPA axis (Section 5.3.2.3) and dopaminergic and GABAergic systems (Sections 5.3.2.2 and 5.3.11.4), which are involved in regulating mood and emotional state.

5.3.6 Psychopathological Effects in Adults

5.3.6.1 Epidemiologic Studies of Psychopathological Effects in Adults

The potential effects of Pb exposure on mood and psychopathological effects (e.g., anxiety, depression, schizophrenia) in adults have been examined less than that in children or cognitive function in adults. However, evaluation of mood states is an integral part of the neurocognitive test battery of the World Health Organization (WHO), and it has been suggested that indices of the Profile Of Mood States may be particularly sensitive to toxicant exposures (Johnson et al., 1987). As with other nervous system endpoints in adults, several studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) found higher prevalence of self-reported mood disorders and anxiety among Pb-exposed workers (n = 43-576, mean concurrent or peak blood Pb levels: 31-79 µg/dL) in association with higher blood Pb levels or compared with unexposed controls (n = 24-181, mean blood Pb levels: 15-38 µg/dL) (Schwartz et al., 2005; Maizlish et al., 1995; Parkinson et al., 1986; Baker et al., 1985; Baker et al., 1984; Lilis et al., 1977). Several studies considered potential confounding by age, sex, education, medical conditions, smoking, and alcohol use, but only Maizlish et al. (1995) examined other occupational exposures. Most studies were cross-sectional, which makes uncertain the temporal sequence between Pb exposure and development of psychopathological effects.

The few studies of adults without occupational Pb exposures participating in NAS and NHANES demonstrated associations of concurrent blood and bone Pb level with psychopathological effects. As bone Pb is a major contributor to blood Pb levels in adults without current occupational Pb exposure, cross-sectional associations with each biomarker may indicate effects of cumulative Pb exposure. These previous and recent cross-sectional studies found associations with adjustment for several potential confounding factors, including age, education, employment status, and alcohol use. Further, the examination of multiple exposures and outcomes in these studies reduces the likelihood of participation conditional on Pb exposure and psychopathological effects.

Analyses of 526 men ages 48-70 years in the NAS indicated associations of both higher concurrent blood (mean: 6.3 µg/dL [SD: 4.16]) and tibia (mean: 21.9 µg/g [SD: 13.5]) Pb levels with higher prevalence of self-reported depression and anxiety (Rhodes et al., 2003). In a recent analysis of 744 NAS men ages 48-94 years, Rajan et al. (2007) found associations of symptoms assessed using the Brief Symptom Inventory with patella and tibia Pb levels. A 14 µg/g increase in tibia Pb level was associated with an increased odds of an anxiety score above the median of 1.18 (95% CI: 0.98, 1.42) and of depression score above the median of 1.16 (95% CI: 0.97, 1.38). Similar effect estimates were found

for patella Pb level. Effect modification by ALAD genotype was not in a consistent direction. For most mood symptoms, tibia bone Pb levels were associated with larger ORs among the 587 men with the ALAD 1-1 genotype. In contrast, ORs for associations between patella Pb levels and symptoms such as depression and positive symptom distress index were larger among the 121 ALAD-2 carriers. In the NAS, effect modification by ALAD genotype also was inconsistent for associations between tibia Pb levels and cognitive performance (Rajan et al., 2008) (Section 5.3.2.7). The relationship between ALAD-2 genotype and Pb bioavailability is not clear (Section 5.2.3.3).

A recent analysis of 1,987 adults ages 20-39 years participating in NHANES 1999-2004 was the largest study of psychopathological effects in adults and included both men and women of multiple races and ethnicities (Bouchard et al., 2009). However, only concurrent blood Pb levels were available for analysis. Various symptoms were examined using the WHO Composite International Diagnostic Interview, which follows DSM criteria. Adults with concurrent blood Pb levels >0.7 µg/dL had higher prevalence of all three self-reported disorders. Adults in the highest quintile of concurrent blood Pb level (≥ 2.11 µg/dL) had the highest OR for major depressive disorder (OR: 2.32 [95% CI: 1.13, 4.75]) and panic disorder (OR: 4.94 [95% CI: 1.32, 18.48]) compared with adults with blood Pb levels <0.7 µg/dL with adjustment for age, sex, race, education, and poverty to income ratio. A monotonic increase in ORs was not found across the quintiles of blood Pb levels. For all endpoints, ORs were larger in analyses excluding current smokers. While associations were found with relatively low concurrent blood Pb levels, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

In analyses of cohorts in California and New England born in the 1950s and 1960s, Opler et al. (2008; 2004) reported associations between higher levels of cord plasma δ-ALA and subsequent diagnosis of schizophrenia spectrum disorder (ascertained using DSM-IV criteria) in adolescence and adulthood. Because of the lack of direct measurements of Pb biomarker levels, post hoc analysis, and limited consideration for potential confounding, firm conclusions are not warranted. Investigators measured δ-ALA levels in stored serum samples as surrogates for Pb exposure only citing previous observations of a high correlation (0.90) between categorized δ-ALA levels (cutpoint 9.05 ng/mL) and blood Pb levels (cutpoint 15 µg/dL). In the California cohort, δ-ALA level ≥ 9.05 ng/mL was associated with schizophrenia spectrum disorder with an OR of 2.43 (95% CI: 0.99, 5.96), with adjustment for maternal age at delivery. In pooled analyses of the California and New England cohorts, δ-ALA level ≥ 9.05 ng/mL was associated with schizophrenia spectrum disorder with an OR of 1.92 (95% CI: 1.05, 3.52), with adjustment for maternal age and education. An adjusted OR was not presented for the New England cohort alone,

and it appeared that the association in the pooled dataset was influenced by that found in the California cohort.

5.3.6.2 Toxicological Studies of Mechanisms of Psychopathological Effects

An environmental origin of schizophrenia was proposed years ago (Tsuang, 2000), and while epidemiologic evidence is inconclusive, toxicological studies have provided indirect evidence to explain how Pb exposure may contribute to schizophrenia development (Figure 5-11). Pb exposure has been shown to reduce function in the NMDA receptor (NMDAR) and decrease hippocampal neurogenesis, which have been associated with schizophrenia-related endpoints. Pb may bind a divalent cation site in the NMDAR and allosterically inhibit glycine binding (Hashemzadeh-Gargari and Guilarte, 1999). NMDAR antagonists have been shown to exacerbate schizophrenia symptoms in affected individuals and induce a schizophrenic phenotype in unaffected subjects (Coyle and Tsai, 2004). Evidence supports a decrease in hippocampal degenerate gyrus (DG) neurogenesis as a mode of action for Pb-associated schizophrenia induction. Developmental Pb exposure inhibits neurogenesis in animal models (Section 5.3.11.9). Decreased neurogenesis is seen in patients with schizophrenia (Kempermann et al., 2008; Reif et al., 2006) and animal models of schizophrenia (Maeda et al., 2007), and clozapine, a treatment for schizophrenia, restores hippocampal DG neurogenesis in animal models of schizophrenia (Maeda et al., 2007) (Figure 5-11). These DG pathways are also NMDAR-dependent.

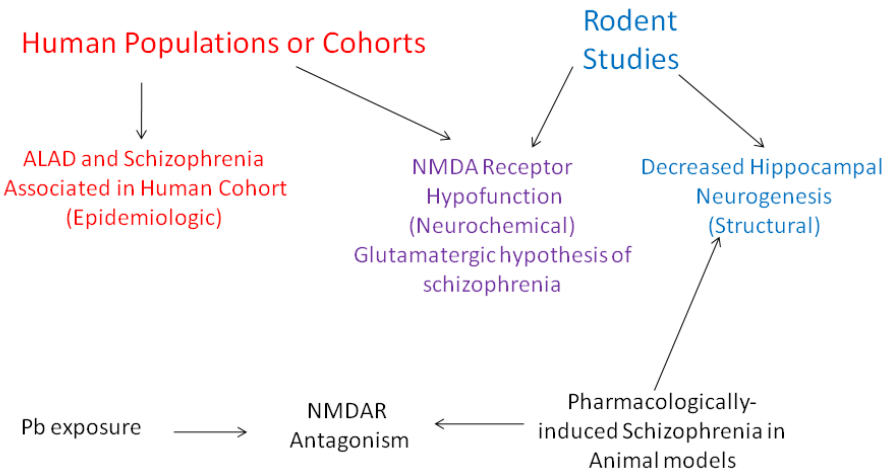

Figure 5-11 Schematic representation of the contribution of Pb exposure to the development of a phenotype consistent with schizophrenia.

5.3.6.3 Summary of Psychopathological Effects in Adults

Studies of Pb exposure and behavior in adults have focused on psychopathological effects rather than aggression and criminal behavior. Evidence links occupational Pb exposure with self-reported mood disorders and anxiety, although the cross-sectional design and potential confounding by other occupational exposures limits the implications. However, supporting evidence is provided by a few but large (n = 744 and 1,787) cross-sectional studies in nonoccupationally-exposed adults that found associations of concurrent blood (Bouchard et al., 2009) and tibia (Rajan et al., 2008) Pb levels with depression and anxiety as assessed with widely-used questionnaires such as the Brief Symptom Inventory and the WHO Composite International Diagnostic Interview. Evidence was provided by the NAS study of men (primarily white) and study of men and women (various races/ethnicities) participating in NHANES, both of which involve the examination of multiple exposures and outcomes. Studies in adults with and without occupational Pb exposure found associations with adjustment for several confounding factors, including age, education, employment status, and alcohol use. The cross-sectional nature of these studies makes uncertain the temporal sequence between Pb exposure and development of psychopathological effects and the critical level, timing, frequency, and duration of Pb exposure. Both blood and bone Pb levels in adults reflect cumulative exposure, and it is uncertain what are the relative contributions of past versus recent Pb exposures to the observed associations.

The epidemiologic evidence is supported by observations that early postnatal (to just after lactation) Pb exposure induces depressive- and anxiety-related phenotypes in animals (Section 5.3.5.2). The mode of action is supported by evidence for Pb-induced changes in the HPA axis and dopaminergic and GABAergic CNS processes, which mediate anxiety and depression. While epidemiologic evidence for Pb-associated schizophrenia is inconclusive, a few toxicological studies have shown that Pb exposure decreases NMDAR function and hippocampal DG neurogenesis, which are found in animal models of schizophrenia (agitation, trouble finding food, reduced swimming behavior).

Epidemiologic evidence indicates associations of Pb biomarker levels with depression and anxiety in children and adults as rated by self, parents, or teachers. Differences in associations for other behaviors may be related to what endpoints are examined. Studies in children and young adults have focused on attention-related behavioral problems and misconduct; studies of older adults did not examine such behaviors. Differential effects in children and adults also may be expected given the predominance of different neurophysiological processes operating at different ages, for example, neurogenesis and brain development in children and neurodegeneration in adults. Differences in the effects

of Pb exposure between children and adults also may be related to differences in Pb exposure profiles by age.

5.3.7 Sensory Organ Function

5.3.7.1 Epidemiologic Studies of Sensory Organ Function in Children

Although not as widely examined as cognitive and behavioral outcomes, several studies found associations of higher blood Pb level with higher hearing thresholds or poorer auditory processing in children, with evidence limited largely to that described in the 2006 Pb AQCD (U.S. EPA, 2006b). The prospective Cincinnati study with repeat measures of blood Pb prenatally to age 5 years provided information on the temporal sequence between Pb exposure and hearing effects and potential critical lifestages of exposure and had extensive consideration for potential confounding. In this cohort, poorer auditory processing in 215 children at age 57 months was associated with higher prenatal maternal, neonatal (10-day), yearly age 1 to 5 year (means: 10.6-18.4 µg/dL), and lifetime average blood Pb levels, with the strongest associations found for neonatal blood Pb level (mean: 4.8 [SD: 3.3] µg/dL). A 1 µg/dL higher neonatal blood Pb level was associated with a 0.20-point ($p \leq 0.01$) and 0.26-point ($p \leq 0.10$) lower score on the total and left ear Filtered Word test (indicating incorrectly identified, filtered, or muffled words), with adjustment for hearing screen, social class, HOME score, birth weight, gestational age, obstetrical complications, and maternal alcohol consumption (Dietrich et al., 1992). Overall, the findings pointed to a stronger effect of Pb exposure in infancy.

Additional support was provided by the large U.S. cross-sectional NHANES II (n = 4,519) (Schwartz and Otto, 1987) and Hispanic Health and Nutrition Examination Survey (HHANES, n = 3,262) (Schwartz and Otto, 1991) studies. The examination of multiple exposures and outcomes in these studies reduces the likelihood of participation conditional on Pb exposure and hearing function. Each study found an association between higher concurrent blood Pb level and higher hearing thresholds in children (ages 4-19 years). In HHNANES, an increase in concurrent blood Pb level (median: 8 µg/dL) from 6 to 18 µg/dL also was associated with a 15% increase in the percentage of children with a substandard hearing threshold (2,000 Hz). Higher concurrent blood Pb level also was associated with higher hearing thresholds across several frequencies in a smaller (n = 155) study of similarly aged (4-14 years) children in Poland with similar blood Pb levels (median: 7.2 µg/dL [range: 1.9-28]) (Osman et al., 1999). In each of the studies in children, associations persisted in analyses restricted to subjects with concurrent blood Pb levels <10 µg/dL. Each of these studies adjusted for different potential confounding

factors, but in stepwise regression analyses, each considered parental education, maternal smoking, nutritional factors, and environmental noise. Across studies, associations were found with adjustment for factors such as age, sex, ethnicity, family income, concurrent or past colds, antibiotic use, degree of urbanization, and Apgar score.
